Chapter 1

Introduction

Most stars lose mass. But the importance of the stellar mass loss for the fate of the star and the rest of the universe differs quite from star to star. Our sun has a negligible mass loss rate while the mass loss from O, B, and Wolf-Rayet stars is very important.

O and B stars are known for a long time. While the first Wolf-Rayet stars were discovered by Wolf & Rayet not before 1867 [70]. The reason for that is that they are so few. Only about 160 Wolf-Rayet stars are known in our galaxy today. Some more we know in the Magellanic clouds and in M33. The most prominent spectroscopical feature of Wolf-Rayet stars are their strong emission lines, while the spectra of most normal stars like our sun are dominated by absorption lines. Similar spectra can be seen in other, less luminous objects like planetary nebulae. The common reason for the strong emission lines is a strong, optically thick outflow of matter. In this thesis we consider only classical Wolf-Rayet stars from the population I when we use the term “Wolf-Rayet star”. Although planetary nebulae have a strong mass outflow as well, the underlying physics and the stellar evolution are different. Wolf-Rayet stars play an especially interesting role in astrophysics. They have the strongest stellar winds. And their winds are strongly enhanced with heavy elements. Their winds contain nearly no hydrogen anymore. The Wolf-Rayet stars of the WN subclass show the chemical composition of the products of the CNO cycle in their winds. While the stars of the WC subclass already show the products of helium burning in their winds. In both cases we have the bare nuclei of more massive progenitor stars. But massive stars do not only enrich the interstellar medium with heavy elements. Additionally the stellar winds carry momentum and kinetic energy. These are very important to trigger e.g. star formation. In this thesis we will only consider blue stars, like O, B, and Wolf-Rayet stars when we talk about “massive stars.” There are massive stars in the red part of the Hertzsprung-Russell diagram as well. But their winds contain dust and are driven in a completely different way. Therefore they are excluded in this thesis.

Significant mass loss as a common phenomenon in massive stars is known only for a short time, because only few massive stars like Wolf-Rayet stars show the typical P-Cygni line profile which is the spectral indicator for strong mass loss. A P-Cygni line is the combination of an emission line with an absorption line connected to the blue wing of the emission line. Both lines come from the same atomic transition. The absorption is caused in the line of sight by the wind material moving towards the observer. This causes the blue-shift of the absorption line. From the blue edge of the absorption line we can therefore derive the maximum velocity in the outflowing matter. The emission line is produced in the wind material which leaves the star roughly perpendicular to the line of sight. Only few, weak P-Cygni lines lie in the optical range. Therefore only few stars with very strong winds like Wolf-Rayet stars are known for long time to have significant mass loss. Thus significant mass loss was considered to be a rare phenomenon in stars. In 1967 Morton [48, 49] used rockets to observe massive stars in the ultraviolet (UV) range. He found that many massive stars show P-Cygni lines in the UV-range. And so mass loss became known as a phenomenon common in massive stars. It became also clear that the absorption of stellar light in atomic lines plays the dominant role in driving these winds. Lucy & Solomon [39] did pioneering theoretical work in this field. Based on their results Castor, Abbott & Klein [16] developed a genius model to describe the line driving mechanism in a simple but in most cases accurate way. We will make extensive use of their model in this thesis.

Today we have much more detailed observations of massive stars in many frequency ranges. This gives us a modern and more detailed picture of their winds. The wind material can today be detected in the radio range, as well. This is more than just a confirmation of the results from P-Cygni lines because normal wind material produces only thermal radio emission. But many massive stars show nonthermal radio emission [4, 5]. This is synchrotron emission, which is a clear evidence for magnetic fields in these winds. Additionally an acceleration mechanism is required to produce high energy particles for the synchrotron emission. The most obvious mechanism is Fermi acceleration in shocks. Shocks appear where the wind collides with the interstellar

medium or with the wind of a neighbouring star (e.g. in binaries). Additionally shocks can be produced by the instability of the wind driving by radiation. Further evidence for the existence of shocks in these winds come from the observation of X-rays in these winds [36]. Detailed analysis of the stellar spectra show strong evidence for wind variability as well. Thus we can not describe the wind of massive stars as stationary, smooth outflows any more. Modern wind models should describe in more detail how these perturbations of the smooth wind are created, how they are amplified, and which consequences they have for the overall wind. From these questions we can learn a lot about these winds.

The first observations of stellar winds were made for our own sun, where due to the short distance we can study wind phenomena much easier and in far more detail than for other stars. L. Biermann was the first who recognized that the tails of the comets, which always point away from the sun, are a clear indication for a permanent matter outflow from the sun [6, 7]. Based on this information Parker developed the first quantitative model for the solar wind. He showed that the hot corona of the sun ($\sim 10^6\text{K}$) must have a permanent matter outflow, because gravity and the interstellar medium can not compensate the high thermal pressure. During the years this basic model has been improved by theory and observation in many ways. Today solar physics is a broad field in astrophysics. Most of these improvements are too detailed to be used for winds from other stars. But one important model, first developed for our sun, will be used in this thesis extensively. It is the model of Weber & Davis [69] for the solar magnetic field. In the solar wind the magnetic field plays only a subordinate role. It merely controls the solar spin-down. The key message of this thesis is that the magnetic field plays an much more important role in the wind physics of massive stars. Massive stars rotate faster and we have many indirect evidence that they have strong magnetic fields [9]. This can enhance the wind drastically. While it seems possible to describe the winds of O and B stars with a purely radiative model [32, 59], this attempt failed for Wolf-Rayet stars.

Models which use the magnetic field as additional ingredient for the winds of massive stars have been developed earlier [20, 61, 62]. But these models suffered from various problems. The strongest limitation to magnetic wind models is the so called spin-down problem. The basic idea of the Weber & Davis models is that open field lines are fixed in the stellar envelope and extend outwards. These field lines co-rotate with the star. Through the Lorentz force they help to push the wind material outside. Through this process the star will lose an extra amount of angular momentum. If the magnetic field is too strong the star will spin down very rapidly. In this case the Weber & Davis mechanism can not play a role in further stages of the stars evolution. Therefore it is important to keep the evolution of a star through its whole life in mind. It is e.g. not clear whether massive stars have a magnetic field through their whole lifetime. It is possible that young, massive stars on the main sequence have a purely radiation driven wind, and therefore radiative wind models are so successful for these stars. Evolved stars like Wolf-Rayet stars, whose wind are not explained yet, may have a magnetic field, which was either generated in a later stage of the stellar evolution or was hidden under the outer layers of the stellar envelope blown away now. These are very speculative ideas. But we are still in an early stage of understanding massive stars.

Another important aspect of magnetic fields in winds of massive stars is the production of cosmic rays. We know from the observation of nonthermal radio emission that we have shocks and a magnetic field in the winds. If the star rotates the magnetic field will be bent into azimuthal direction far away from the star. If we combine such a field configuration with shock running in radial direction we get an optimal configuration for particle acceleration due to the Fermi mechanism. The high energy particles produced here gyrate in the magnetic field and produce the observed nonthermal radio emission. But high energy particles, especially protons and nucleons, can also escape from the system and contribute to the galactic cosmic ray spectrum. This is the basic concept of Biermann & Cassinelli [8, 9], who combined several aspects of magnetic fields in the winds of massive stars into a self-consistent picture. This work gave rise to the initial concept of this thesis.

In this thesis we analyze several aspects of magnetic fields in stellar winds. The fundament for these models are the improved version of the fast magnetic rotator model developed by Biermann & Cassinelli [8, 9]. The first major part of this thesis is a model for the influence of the magnetic field on the radiative instability in the wind. Already very early it became clear that line driven winds are unstable [39, 46]. But all previous attempts to use these instabilities to explain the thick and fast winds, we observe in massive stars, failed. We found that this is due to the neglect of the magnetic field. Previous work concentrated on the effect of radiation and found that the instability produces inward running waves [52]. These waves can help to explain many details in the spectra of massive stars. But they do not help to explain basic wind parameters like the high observed terminal wind velocities. We found that a magnetic field turns the waves into outward running waves [67], which can explain the high observed terminal velocities with moderate magnetic fields. The latter is very important to keep the spin-down problem under control.

In the second major part of this thesis we extend the basic wind model to take the wind outside the equatorial plane into account. Older wind models separate into two classes. The first class of models ignores rotation and the magnetic field. These models treat all quantities as only radius dependent. Thus they are one dimensional

and strictly spherical. Most purely radiation driven wind models belong to this class. The second class of models treats rotation and often magnetic fields. They assume only rotational symmetry but restrict themselves to the equatorial plane. Through this restriction they are essentially one dimensional as well. Strong assumptions are necessary to estimate the wind outside the equatorial plane. Our wind model keeps the simplicity of an one dimensional wind model but allows to explore the wind outside the equatorial plane. This gives us much more confidence in wind models with rotation. The second important aspect of our extension is, that this model can now be used to calculate winds which do not blow in the equatorial plane at all. For such winds the old equatorial models are meaningless. This is the large family of winds from accretion disks, which often turn into jets close to the polar axis. Such winds appear in many astrophysical objects from young stellar objects (YSO) to active galactic nuclei (AGN). Due to this broad applicability we expect many interesting results from our wind model in the future.

In Chap. 2 we start our discussion with some basic concepts explained at the wind model of Parker. In Chap. 3 we give a short introduction to the theory of line driven winds. Since this thesis concentrates on the role of the magnetic field only the basic concepts for our own usage are given here. In Chap. 4 the wind equations for the equatorial plane are derived. These equations are already slightly generalized compared to the equations of Biermann & Cassinelli by the fact that they incorporate the effect of a wind compressed or diluted in the equatorial plane. In Chap. 5 we combine the results from the two previous chapters for some initial wind models, which allow the comparison with previous models. In Chap. 6 we derive our model for waves in magnetic winds from massive stars and give numerical results for a generic model star. Chap. 7 contains our model for the wind outside the equatorial plane. Some initial numerical results are given as well. In Chap. 8 we summarize our results in this thesis. The appendices contain some extra numerical and mathematical material for the non-equatorial wind model from Chap. 7.

Chapter 2

Introduction to stellar wind theory

The first stellar wind models were developed for our sun. L. Biermann [6, 7] first proposed a steady hydrodynamical outflow from the sun to explain the direction of the cometary tails. Based on this idea Parker [58] showed that the sun indeed can not have a stationary atmosphere. Due to the high temperature of the corona a stationary atmosphere would have a high finite pressure at infinity. This pressure could not be compensated by the interstellar medium. A continuous expansion of the solar atmosphere is the direct consequence. Parker's solar wind is only driven by thermal pressure. This leads to a simple model which nevertheless gives important insight in the physics of stellar winds in general. Therefore the important parts of Parker's model will be outlined in this chapter.

The solar wind has a velocity of approximately 300 – 800 km/s at the earth's orbit. Even very early type stars produce only a wind of up to 3500 km/s much smaller than the speed of light. Therefore nonrelativistic physics is sufficient to describe these stellar winds and will be used in this thesis.

For this introducing discussion to stellar winds it is sufficient to study the average, large scale structure of the solar wind. This allows us to use the theory of hydrodynamics, and later magnetohydrodynamics, as basis for our models. Hydrodynamics can be used whenever the relevant scales of the model are larger than the mean free path λ for collisions between molecules. At the base of the solar wind we have roughly $\lambda(3R_\odot) = 4 \cdot 10^{-2} R_\odot$. At the earth's orbit λ has increased to $\lambda(1\text{AU}) = 1.5\text{AU}$. Here and further out rigorous treatment using the Fokker-Planck equation would be better. But this is beyond the scope of this thesis. This problem is relaxed by the fact that the solar wind has a magnetic field. The magnetic field forces the ionized wind particles to gyrate around the field lines. This effect increases the probability to hit an other particle and allows the particles to be scattered at field irregularities, so that the hydrodynamical equilibrium is reestablished. Furthermore the wind of early type stars is much denser than the solar wind. This leads much shorter mean free paths and justifies the usage of hydrodynamics as well.

The hydrodynamical wind is described by the conservation of mass

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (2.1)$$

momentum

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \nabla) \mathbf{v} = \mathbf{F}_{\text{ext}}, \quad (2.2)$$

and energy

$$\rho \left(\frac{\partial e}{\partial t} + (\mathbf{v} \cdot \nabla) e \right) + P(\nabla \cdot \mathbf{v}) = -\nabla \cdot \mathbf{q}_c, \quad (2.3)$$

where ρ is the matter density, t the time, $\mathbf{v}$ the velocity of the bulk matter, $\mathbf{F}_{\text{ext}}$ the sum of all external force densities, e the internal energy per unit mass, P the thermal pressure, $\mathbf{q}_c = -\kappa_c \nabla T$ the conductive energy flux, κ_c the thermal conductivity, and T the temperature. If we assume that the star does not rotate and that the wind is stationary, the whole system reduces to one dimension

$$\dot{M} = 4\pi \rho v_r r^2 = \text{const} \quad (2.4)$$

$$\rho v_r v_r' = F_{\text{ext}}, \quad (2.5)$$

where $'$ denotes the derivative with respect to the radius r . $\dot{M}$ is the mass loss rate and v_r is the radial component of the wind velocity $\mathbf{v}$. The external forces are created by radiation pressure from the stellar light, thermal pressure, interaction of the gas with waves and shocks, and gravitation. We will discuss radiation pressure as a major component of early type star wind in Chap. 3. The creation of waves and shocks by the

instability of radiation pressure in a magnetic wind is the subject of Chap. 6. Other sources for shocks and waves are e.g. discussed in [15]. The influence of waves and shocks on the average wind through Eq. 2.2 was analysed by Koninx [30]. The gravitational potential derives from Poissons equation

$$\nabla^2 \Phi = -4\pi G \rho, \quad (2.6)$$

where G is the gravitational constant. The contribution of the wind mass

$$M_{\text{wind}} = \int \rho dV \approx \dot{M} \frac{r_{\infty}}{v_r} \quad (2.7)$$

is negligible compared to the stellar mass, where r_{∞} is the radius of the heliosphere. For the sun we find $M_{\text{wind}} \approx 10^{-12} M_{\odot}$, where $M_{\odot}$ is the solar mass. All normal stars are also reasonably spherically symmetric. We can therefore approximate the gravitational potential by

$$\Phi = -\frac{GM}{r}, \quad (2.8)$$

where M is the stellar mass. We now express the thermal pressure P by the isothermal speed of sound v_s

$$P = v_s^2 \rho \quad (2.9)$$

$$v_s^2 = \frac{k_B T}{m}, \quad (2.10)$$

where m is the average mass of the wind particles. If we use gravitation and thermal pressure as the only relevant forces, as Parker did

$$F_{\text{ext}} = -\rho \Phi' - P', \quad (2.11)$$

we can write the momentum equation as

$$v_r v_r' = \frac{f(r)}{g(r, v_r)} = \frac{\frac{2v_s^2}{r} - v_s'^2 - \frac{GM}{r^2}}{1 - \frac{v_s^2}{v_r^2}}. \quad (2.12)$$

In the general case this ordinary differential equation has to be solved simultaneously with an equation for $T(r)$ which can be derived from Eq. 2.3. This can be found in [58, 45]. For our discussion it is sufficient to analyze the isothermal approximation. In this case g in Eq. 2.12 depends only on v_r . For $v_r > v_s$, g is larger than zero and otherwise smaller than zero. $f(r)$ changes its sign at the Parker radius

$$r_c = \frac{GM}{2v_s^2}. \quad (2.13)$$

This leads to a classical family of solutions. The members with $v_r > 0$ are sketched in Fig. 2.1. If a solution reaches $|v_r| = v_s$ at a radius $r \neq r_c$, v_r' becomes infinite. This leads to double valued solutions like solutions 5&6. These are unphysical for a stationary wind. If a solution passes through the critical point $|v_r| = v_s$, $r = r_c$, l'Hospital's rule gives

$$v_r'(r_c) = \pm \frac{2v_s^3}{GM}, \quad (2.14)$$

which leads to two solutions. Solution 1 is subsonic at the solar surface and continuously accelerates up to supersonic velocities. This solution was proposed by Parker for the solar wind. Solution 2 describes a wind which has for some reason a very high velocity at the solar surface. This does not fit the observation there. The same is true for solution 4, which is supersonic at all radii. Solution 3 did indeed fit all observations in 1958. It was proposed by Chamberlain [17] as solar *breeze*. Finally the question was solved in favour of the transonic *winds* by observations from satellites, which found a supersonic plasma at the earth's orbit. The solutions with negative velocities can be interpreted as accretion scenarios [29, 44].

Critical points are very useful for the solution of wind equation, because they contain extra information. Equation 2.12 is a single ordinary differential equation of first order. For such an equation it is normally necessary to specify v_r at one point in order to select a unique solution from the infinite family of possible solutions. Once we know from physical arguments that the solution has to go through the critical point, only a small finite number of solutions remain. This becomes important in the case of stellar winds, where less parameters are accessible for direct observation than in the case of our sun.

The isothermal model has the advantage that neglecting the energy balance simplifies the mathematics. Physically it means that we implicitly introduce additional energy sources and sinks to maintain the constant

Figure 2.1: The solutions of Parker's isothermal wind equation

temperature. Close to the sun, where the temperature changes only by one order of magnitude between the corona and the earth's orbit, this is a reasonable approximation. When we go further out the wind has to cool down adiabatically finally. In the isothermal case Eq. 2.12 can be readily integrated to

$$\left(\frac{v_r}{v_s}\right)^2 - 2 \ln \left(\frac{v_r}{v_s}\right) = 4 \ln \left(\frac{r}{r_c}\right) + 4 \frac{r_c}{r} + C. \quad (2.15)$$

For $r \rightarrow \infty$ and $v_r \gg v_s$ this leads to $v_r = 2v_s \ln^{0.5}(r/r_c) \rightarrow \infty$, because we add an infinite amount of thermal energy to maintain the constant temperature at infinity.

Real stellar winds do not extend to infinity, but they collide with the interstellar medium. This happens when the ram pressure equals the pressure of the interstellar medium. Therefore all numerical models for stellar wind compute the wind only up to a large but finite radius. This radius should be chosen so that it is larger than any radius relevant in the wind. In Chap. 4 we will use $u \sim r^{-1}$ as spatial coordinate. In this case it is mathematically possible to extend the computation to infinity in the mathematical sense. This can not be done using the isothermal approximation. But since the wind is terminated in the real world by the collision with the interstellar medium anyway, we will compute our wind models only to a large radius using the isothermal approximation.

In this chapter we established the fundamental framework for our stellar wind models. We will use nonrelativistic hydrodynamics or magnetohydrodynamics (MHD) in the stationary or quasi stationary form to describe stellar winds. This thesis emphasizes the role of the magnetic field. Thus we treat the wind as isothermal and do not go into the details of radiation transfer theory.

Chapter 3

Stellar radiation and winds

3.1 Introduction

Photons carry momentum and energy. Both can be exchanged with matter. Therefore it seems quite obvious that the stellar light can play an important role in stellar wind physics. Unfortunately, the detailed treatment of this process is very complicated.

We start our discussion with some basic definitions from radiation theory following the description of Mihalas [45] and Falcke [18]. The specific radiation intensity

$$I_\nu = \frac{dE_{\text{rad}}}{d\nu dt \mathbf{n} \cdot d\mathbf{a} d\Omega} \quad (3.1)$$

is the differential energy dE_{rad} per unit frequency ν and time t , which is emitted from an area of size da oriented in direction $d\mathbf{a}$ into a solid angle $d\Omega$ in direction $\mathbf{n}$. If the radiation with solid angle $d\Omega$ and direction $\mathbf{n}$ passes through the area $d\mathbf{a}$ along a distance ds , and the volume $dV = d\mathbf{a} ds$ is filled with matter of density ρ , the energy

$$dE_{\text{abs}} = I_\nu \rho \kappa_\nu d\Omega d\nu dt \mathbf{n} \cdot d\mathbf{a} ds \quad (3.2)$$

is absorbed. The opacity κ_ν can be equivalently expressed by the total cross section for absorption

$$\sigma_\nu = m \kappa_\nu. \quad (3.3)$$

The momentum transfer $d\mathbf{p} = \mathbf{n} dp$ per unit volume and due to the absorption can be expressed by

$$dp = \frac{dE_{\text{abs}}}{c dV dt}. \quad (3.4)$$

This assumes that all photons which are emitted from the matter, including scattered photons, are emitted isotropically. Therefore their net momentum is zero and can be neglected in the momentum transfer between radiation and matter. This absorption approximation is sufficient for our models. More elaborate radiation transfer models, which include non-isotropic emission, have been calculated by Gayley et al. [23] and others. To obtain the total radiative acceleration we have to integrate dp over frequency and the angle of incoming radiation:

$$g_{\text{rad}} = \frac{1}{\rho} \int \int dp \quad (3.5)$$

$$= \int \int I_\nu \kappa_\nu \mathbf{n} d\Omega d\nu \quad (3.6)$$

$$= c^{-1} \int_0^\infty F_\nu \kappa_\nu d\nu \quad (3.7)$$

σ and κ are complicated functions of temperature, density, chemical composition, frequency, and the intensity I_ν . Since the radiation and matter influences each other while the radiation passes through many layers of material, we end up with an enormous nonlocal set of equations. Solving this problem rigorously leads to good quantitative results for the radiation transfer but also needs an enormous effort [32, 59]. This is beyond the scope of this thesis. Therefore it is necessary to simplify the problem to a level which is reasonably close to physical reality but simple enough. For the treatment of hot star winds at this level there are two important models for the interaction of radiation and wind: Thompson scattering and line absorption.

In Sect. 3.2 we discuss Thompson scattering as a very simple mechanism for the interaction between matter and radiation. In Sect. 3.3 we discuss how photon absorption in atomic lines can be described in a simple model. And finally we discuss in Sect. 3.4 the critical point in solutions for these radiation driven winds.

3.2 The Thompson wind

Due to the high temperature in the wind of hot stars and due to the strong ultraviolet radiation field, the matter in the wind is highly ionized. This leads to a large number of free electrons. Free electrons are, compared to atoms and molecules, very simple objects. Their total cross section for scattering of radiation is

$$\sigma_{\text{Th}} = \frac{8\pi}{3} r_{\text{ce}}^2 = 6.65 \cdot 10^{-25} \text{cm}^2 \quad (3.8)$$

$$r_{\text{ce}} = \frac{e^2}{m_e c^2} \quad (3.9)$$

where r_{ce} is the classical electron radius. The angular dependence of the differential cross section and the backscattering of the photons can be neglected for our treatment (absorption approximation). To calculate the opacity we need to know the number of free electrons per unit mass. Since the wind can be assumed to be fully ionized this depends only on the ratio of protons (and electrons) to nucleons. For hydrogen this is 1, for helium and heavier elements it is 0.5. This leads to

$$\kappa_{\text{Th}} = (1 + X) \frac{\sigma_{\text{Th}}}{2m_p} \approx 0.2(1 + X) \frac{\text{cm}^2}{\text{g}}, \quad (3.10)$$

where X is the number fraction of hydrogen in the wind. Since κ_{Th} is independent of ν , we can integrate Eq. 3.7 directly. If we assume that the wind is optically thin, so that the flux F_ν depends only on the geometry, we get

$$g_{\text{Th}} = \frac{\kappa_{\text{Th}} L}{4\pi r^2 c}, \quad (3.11)$$

where

$$L = \int_0^\infty \int F_\nu d\Omega d\nu = 4\pi r^2 F \quad (3.12)$$

is the total luminosity of the star. Here we assumed that the star is point like. This simplifies the integration over the angle of the incoming photons. Models which take the finite size of the star into account had been calculated for the CAK-model [19, 60]. The Thompson radiation pressure has the same radial dependence than gravity. So if we add Thompson scattering to the external force balance (Eq. 2.11) we get

$$F_{\text{ext}} = \rho(g_{\text{grav}} + g_{\text{Th}}) + F_{\text{pressure}} \quad (3.13)$$

$$= -\frac{GM\rho}{r^2}(1 - \Gamma) - P' \quad (3.14)$$

$$\Gamma = \frac{L}{L_E} = \frac{\kappa_{\text{Th}} L}{4\pi GMc}. \quad (3.15)$$

Γ is the well known Eddington factor, which describes the modification to gravity by Thompson scattering. If Γ would exceed 1 the star would disintegrate, because the radiation pressure overcomes gravity. This is known as the Eddington limit. Since the Thompson model is so simple it can be integrated without extra effort in every wind model.

3.3 The theory of Castor, Abbott & Klein

In the last section we saw that a sufficient high opacity can drive any wind. But the Thompson opacity is not high enough to explain the strong winds we see in many hot stars. Already in the twenties Johnson [28] and Milne [46, 47] proposed absorption in spectral lines as an additional mechanism to drive outflows from stars. The line opacity, especially in resonance lines, is much higher than the continuum opacity. But this is much more difficult to treat due to the complicated interaction between the radiation intensity, as function of frequency and radius, and the opacity depending on individual excitation levels of the atoms. If the wind is very thin (i.e. the radiation is not strongly attenuated - even in lines) we could use an opacity averaged in frequency like the Rosseland opacity to calculate a ‘gray’ wind model. This would just replace the low Thompson opacity by the higher Rosseland opacity. But in the wind of hot stars many lines become optically thick. The strong dependency of the line opacity and the radiation intensity on frequency requires to take the Doppler effect for accelerating winds into account. Sobolev [68] did pioneering work to find a simple formalism to describe this mechanism. Lucy and Solomon [39] were the first who applied this idea to hot stars shortly after Morton [48, 49] had observed P-Cygni profiles in the UV-spectra of such stars. But their model used only a few resonance lines and therefore gave much smaller mass loss rates than observed. Castor Abbott, and Klein [13, 16] (CAK) solved

this problem by including a large number of lines. Nevertheless they managed to keep the theory simple by encapsulating the complicated atomic physics in a simple fit formula. This allows us to use this formula in this project.

We do not need the full details of this theory. Therefore we follow here the derivation of Owocki [51]. The CAK-theory is a hydrodynamical theory. It assumes that the momentum which is absorbed by some heavy elements is distributed among the whole wind material. This distinguishes it from the early work by Johnson and Milne, who assumed the heavy elements escape from the star while the hydrogen remains bounded. The second assumption is that the temperature and any nonthermal population of the atomic levels are known in advance. This fixes the opacity of the wind material. The CAK-theory takes into account, that optically thick lines can shadow themselves from the stellar light, and that this effect can be suppressed by the Doppler-shift in the expanding wind.

We start the derivation with a single line of opacity

$$\kappa_\nu = \kappa_L \phi(x) \quad (3.16)$$

$$x = \frac{\nu - \nu_L}{\nu_L} \frac{c}{v_{\text{th}}} \quad (3.17)$$

$$v_{\text{th}} = \sqrt{\frac{2k_B T}{m_p}}, \quad (3.18)$$

where x is the deviation from the line frequency ν_L in units of the Doppler shift due to the thermal motion v_{th} . Here κ_L is the line opacity, $\phi(x)$ is the normalized line profile function, c is the speed of light, k_B is the Boltzmann constant, and m_p is the mass of the proton. The deviation of the mean mass m of the wind particles from the proton mass is later incorporated in the CAK parameter α_{cak} and k_{cak} . If we neglect now the momentum of the emitted photons, we can express the radiative acceleration of this line resulting from a flux F_ν by the momentum of the absorbed photons

$$g_L(r, \nu_L, \kappa_L) \approx g_{\text{abs}}(r, \kappa_L) = \int_0^\infty \kappa_L \phi\left(x - \frac{v_r(r)}{v_{\text{th}}}\right) \frac{F_\nu}{c} \frac{\nu_L v_{\text{th}}}{c} e^{-\tau(x,r)} dx, \quad (3.19)$$

where we have taken the attenuation of the flux F_ν by the optical depth

$$\tau(x, r) = \int_R^r \kappa_L \rho(\tilde{r}) \phi\left(x - \frac{v_r(\tilde{r})}{v_{\text{th}}}\right) d\tilde{r} \quad (3.20)$$

$$= \int_{x - \frac{v_r(r)}{v_{\text{th}}}}^x \kappa_L \rho \phi(\tilde{x}) \frac{v_{\text{th}}}{v'_r} d\tilde{x} \quad (3.21)$$

into account, where R is the radius of the stellar surface ($v_r(R) \approx 0$) and $\tilde{x} = x - (v_r(\tilde{r})/v_{\text{th}})$ the frequency in the comoving frame. The line profile function $\phi(x)$ is sharply peaked at $x = 0$ and therefore only the small spatial region of the wind with $|x - v_r(\tilde{r})/v_{\text{th}}| \lesssim 1$ will contribute to the integral in Eq. 3.21. The thickness of this region is given by the Sobolev length

$$L_S = \frac{v_{\text{th}}}{v'_r(r)} \quad (3.22)$$

with the velocity gradient of the wind

$$v'_r = \frac{dv_r}{dr}. \quad (3.23)$$

The important contribution of Sobolev at this point was the observation that $\rho(\tilde{r})/v'_r(\tilde{r})$ is approximately constant over this region of the wind. Since we have a single line wind, where the same line causes the flux attenuation and the wind acceleration, both effects take place at approximately the same radius r . We can therefore approximate $\rho(\tilde{r})/v'_r(\tilde{r})$ by $\rho(r)/v'_r(r)$. This allows us to draw this term out of the integral

$$\tau(r, x) \approx \tau_L \int_{x - \frac{v_r(r)}{v_{\text{th}}}}^\infty \phi(\tilde{x}) d\tilde{x}, \quad (3.24)$$

where we have introduced the Sobolev optical depth of a single line

$$\tau_L(r) = \frac{\kappa_L \rho v_{\text{th}}}{v'_r}. \quad (3.25)$$

For convenience we shift now to the comoving frame at radius r by $\hat{x} = x - v_r(r)/v_{\text{th}}$ to solve Eq. 3.19 analytically

$$g_L(r, \nu_L, \kappa_L) \approx \frac{F_L \kappa_L v_{\text{th}} \nu_L}{c^2 \tau_L} \int_{-\infty}^{\infty} \tau_L \phi(\hat{x}) \times \exp\left(-\tau_L \int_{\hat{x}}^{\infty} \phi(\tilde{x}) d\tilde{x}\right) d\hat{x} \quad (3.26)$$

$$\approx \frac{F_L \kappa_L \nu_L v_{\text{th}}}{c^2} \frac{1 - e^{-\tau_L}}{\tau_L}. \quad (3.27)$$

In the case of an optically thin line $\tau_L \ll 1$ we find

$$g_{\text{thin}} = \frac{F_L \kappa_L \nu_L v_{\text{th}}}{c^2}. \quad (3.28)$$

In the optically thick case $\tau_L \gg 1$ we find

$$g_{\text{thick}} = \frac{g_{\text{thin}}}{\tau_L} = \frac{F_L \nu_L}{c^2 \rho} v'_r. \quad (3.29)$$

This expression is independent of κ_L because the thick line will absorb all the photons in its frequency range anyway. But g_{thick} depends on the velocity gradient v'_r , because v'_r describes how efficiently the line can escape its own shadow and therefore can absorb new photons at a different Doppler shifted frequency.

The major improvement of Castor, Abbott, and Klein was to take many lines into account by summing Eq. 3.19 for many lines. This includes the assumption that different lines do not overlap in frequency even taking the Doppler shift due to the wind velocity into account. For a real line list this computation can only be done numerically. It is then possible to encapsulate the atomic physics of the line list in a function $M(t)$ called the *force multiplier*. CAK found that this force multiplier can then be approximated by

$$M(t) = k_{\text{cak}} t^{-\alpha_{\text{cak}}}, \quad (3.30)$$

where.

$$t = \frac{\kappa_{\text{Th}} \rho v_{\text{th}}}{v'_r} \quad (3.31)$$

is the line independent Sobolev optical depth. CAK [16] found $k_{\text{cak}} = 1/30$ and $\alpha_{\text{cak}} = 0.56$. Later Abbot [2] tabulated improved values for k_{cak} and α_{cak} .

The results given in Eq. 3.30 can be obtained analytically if we assume that the lines have a flux-weighted number distribution that has a power law in opacity given by

$$N(\nu_L, \kappa_L) = \frac{F}{\nu_L F_L} \frac{1}{\kappa_0} \left(\frac{\kappa_L}{\kappa_0} \right)^{\alpha_{\text{cak}} - 2}, \quad (3.32)$$

where F is the total radiation flux and κ_0 is a normalisation constant. We can now incorporate this expression in Eq. 3.19 and integrate over opacity.

$$g_{\text{cak}}(r, v_r, v'_r) = \int_0^{\infty} N(\nu_L, \kappa_L) g_L(r, \nu_L, \kappa_L) d\kappa_L \quad (3.33)$$

$$\approx \frac{F v_{\text{th}} \kappa_0}{c^2} \left(\frac{v'_r}{\kappa_0 \rho v_{\text{th}}} \right)^{\alpha_{\text{cak}}} \times \int_{-\infty}^{\infty} \int_0^{\infty} \tau_L^{\alpha_{\text{cak}} - 1} e^{-\tau(\hat{x}, r)} d\tau_L \phi(\hat{x}) d\hat{x} \quad (3.34)$$

$$\approx \frac{F v_{\text{th}} \kappa_0}{c^2} \left(\frac{v'_r}{\kappa_0 \rho v_{\text{th}}} \right)^{\alpha_{\text{cak}}} \Gamma(\alpha_{\text{cak}}) \times \int_{-\infty}^{\infty} \left(\int_{\hat{x}}^{\infty} \phi(\tilde{x}) d\tilde{x} \right)^{-\alpha_{\text{cak}}} \phi(\hat{x}) d\hat{x} \quad (3.35)$$

$$\approx \frac{F v_{\text{th}} \kappa_0}{c^2} \frac{\Gamma(\alpha_{\text{cak}})}{1 - \alpha_{\text{cak}}} \left(\frac{v'_r}{\kappa_0 \rho v_{\text{th}}} \right)^{\alpha_{\text{cak}}} \quad (3.36)$$

$$\approx \frac{F \kappa_{\text{Th}}}{c} M(t), \quad (3.37)$$

where $\Gamma(\alpha_{\text{cak}})$ is the complete Gamma function. Here we find the relation between κ_0 and k_{cak} :

$$k_{\text{cak}} = \frac{v_{\text{th}}}{c} \left(\frac{\kappa_0}{\kappa_{\text{Th}}} \right)^{1 - \alpha_{\text{cak}}} \frac{\Gamma(\alpha_{\text{cak}})}{1 - \alpha_{\text{cak}}} \quad (3.38)$$

If we include g_{cak} and g_{Th} in the wind equation we get different analytical conditions for a complete physical solution than in the case of a Parker wind. The reason for this is that g_{cak} depends additionally on the local wind acceleration. To analyze the solutions we rewrite the wind equation (Eq. 2.12) to

$$A(r, v_r)v_r' + B(r) = C(r, v_r)v_r'^{\alpha_{\text{cak}}} \quad (3.39)$$

$$A = v_r - \frac{v_s^2}{v_r} \quad (3.40)$$

$$B = \frac{GM}{r^2}(1 - \Gamma) - 2\frac{v_s^2}{r} + v_s^{2\prime} \quad (3.41)$$

$$C = \frac{\kappa_{\text{Th}}L}{4\pi r^2 c} k_{\text{cak}} \left(\frac{1}{\kappa_{\text{Th}} \rho v_{\text{th}}} \right)^{\alpha_{\text{cak}}} \quad (3.42)$$

$$= \frac{GM\Gamma k_{\text{cak}}}{r^2} \left(\frac{4\pi r^2 v_r}{\kappa_{\text{Th}} \dot{M} v_{\text{th}}} \right)^{\alpha_{\text{cak}}}. \quad (3.43)$$

Equation 3.39 is an implicit differential equation, which in general can not be solved analytically. But this is one of the minor numerical problems in CAK wind models. In the case of an isothermal wind we can simplify these equations by substituting $u = -1/r$, $w = v_r^2/2$, and $\dot{w} = (dw/du)$:

$$\bar{A}(w)\dot{w} + \bar{B}(u) = \bar{C}\dot{w}^{\alpha_{\text{cak}}} \quad (3.44)$$

$$\bar{A}(w) = 1 - \frac{v_s^2}{2w} \quad (3.45)$$

$$\bar{B}(u) = GM(1 - \Gamma) + 2v_s^2 u \quad (3.46)$$

$$\bar{C} = GM\Gamma k_{\text{cak}} \left(\frac{4\pi}{\kappa_{\text{Th}} \dot{M} v_{\text{th}}} \right)^{\alpha_{\text{cak}}}. \quad (3.47)$$

In the case of a cold wind without thermal pressure ($v_s = 0$) Eq. 3.44 becomes independent of r . Therefore $\dot{w} = (dw/du)$ is independent of r as well. This leads to the often used velocity law

$$v_r(r) = v_\infty \sqrt{1 - \frac{R}{r}} \quad (3.48)$$

$$v_\infty = \sqrt{\frac{2\dot{w}}{R}}, \quad (3.49)$$

where R is the stellar radius. Since in this case $A = 1$ and $B = GM(1 - \Gamma)$ are larger than zero, we can have two (Fig. 3.1.A), one (Fig. 3.1.B), or no (Fig. 3.1.G) solutions for $\dot{w}$ depending on the value of $C(\dot{M})$. The case of one solution is special, because it has the minimum value for $C(\dot{M})$ and therefore the maximum value of $\dot{M}$. The unique value for $\dot{w}$ in this case leads to

$$\dot{M}_{\text{max}} = \frac{4\pi GM}{\kappa_{\text{Th}} v_{\text{th}}} \alpha_{\text{cak}} (k_{\text{cak}} \Gamma)^{1/\alpha_{\text{cak}}} \left(\frac{1 - \alpha_{\text{cak}}}{1 - \Gamma} \right)^{(1 - \alpha_{\text{cak}})/\alpha_{\text{cak}}} \quad (3.50)$$

$$v_\infty(\dot{M}_{\text{max}}) = \sqrt{\frac{\alpha_{\text{cak}}}{1 - \alpha_{\text{cak}}} \frac{2GM(1 - \Gamma)}{R}}. \quad (3.51)$$

This case is often referred to as the analytical CAK-solution. Nevertheless this situation is not satisfying, because solutions with lower mass loss rates are not excluded by any physical argument.

3.4 The CAK point

For a unique solution with a unique value for $\dot{M}$ we have to take the thermal pressure into account. Since α_{cak} is between 0 and 1, Eq. 3.1 can have no, one, or two solutions for v_r' depending on the values of A , B . The possible cases are sketched in Fig. 3.1. If C is zero we have the Parker or Thompson wind as limiting case. At $r = \infty$ we have a negative value for B . This requires $A > 0$ as plotted in Fig. 3.1.D and therefore a supersonic wind. Close to the star the gravity term in Eq. 3.41 will dominate and cause a positive value for B . This transition from Fig. 3.1.D to Fig. 3.1.A takes place in the supersonic part of the wind ($A > 0$). Otherwise we would end

Figure 3.1: The possible solutions of Eq. 3.39: The left hand side of Eq. 3.39 is linear in v'_r : $A v'_r + B$, while the right hand side: $C v_r'^{\alpha_{\text{cak}}}$ depends on v'_r roughly like $\sqrt{v'_r}$ because α_{cak} is between 0 and 1. But A and B can have either sign (Eqs. 3.40&3.41) depending on the values of r and $v_r(r)$. From Eq. 3.43 we see that C is always positive. In Figs. A–H we sketch the left hand side and the right hand side of Eq. 3.39 (ordinate) as function of v'_r (abscissa). r and v_r are kept constant in each figure. A solution for Eq. 3.39 is given at every value of v'_r where the two curves intersect. In Fig. A Eq. 3.39 has two solutions. In Figs. B–F Eq. 3.39 has one solution. And in Figs. G&H Eq. 3.39 has no solution. In general the coefficients A and B are not constant in a single wind solution. Thus for different radii different of the figures sketched here may apply in the same wind solution. For a physical wind solution r and v_r and thus A and B are continuous everywhere. Therefore the transition between these different figures has to be continuous as well. A nonmagnetic wind passes from the base of the wind to infinity through the following sequence: C–E–A–B(here is the CAK critical point)–A–D. See Sect. 3.4 for details. The case of Fig. F appears only if magnetic fields are included (Chap. 5). In this case A and B are infinite at the Alfvénic point.

up with the situation of Fig. 3.1.H where no solution for v'_r can be found. In the case of Fig. 3.1.A we have two possible solutions. But the continuous transition from Fig. 3.1.D allows only the larger value of v'_r .

If we use the CAK-model in the subsonic part of the wind we get a negative value for A . Therefore B must be positive and we have the unique solution for v'_r , which is sketched in Fig. 3.1.C. At the sonic point ($A = 0$, Fig. 3.1.E) the solution switches to Fig. 3.1.A. But now the proper solution for v'_r is the lower value, because only this matches continuously the unique solution at the sonic point.

If we want a continuous steady state solution, which extends from the base of the wind ($v_r \ll v_s$) to $r = \infty$, we have to connect the solution branches discussed above in a proper way. This can only happen if the solution passes through a point where Fig. 3.1.B applies. Only here we can shift v'_r continuously from the lower value in Fig. 3.1.A to Fig. 3.1.B and then to the higher value in Fig. 3.1.A. This point is the *critical CAK-point*. It fixes the whole solution. The best way to solve Eq. 3.39 numerically is to find the critical CAK-point and to integrate Eq. 3.39 from there to the base of the wind and to $r = \infty$.

The critical CAK-point is specified by four quantities: $\dot{M}$, r_c , v_{rc} , and v'_{rc} . Therefore we need four conditions to find the critical CAK-point. The first one is Eq. 3.39. From Fig. 3.1.B we see that both sides of Eq. 3.39 have the same inclination when they are plotted as function of v'_r . This happens only in Fig. 3.1.B and is therefore the second condition:

$$A(r_c, v_{rc}) = \alpha_{\text{cak}} C(r_c, v_{rc}) v'_{rc}{}^{\alpha_{\text{cak}}} \quad (3.52)$$

A physical solution for v_r should be smooth everywhere. This allows us to differentiate Eq. 3.39 totally with respect to r :

$$\begin{aligned} \left(\frac{\partial A}{\partial r} + \frac{\partial A}{\partial v_r} v'_r \right) v'_r + A v''_r + \frac{\partial B}{\partial r} = \\ \left(\frac{\partial C}{\partial r} + \frac{\partial C}{\partial v_r} v'_r \right) v'^{\alpha_{\text{cak}}} + \alpha_{\text{cak}} C v'^{(\alpha_{\text{cak}}-1)} v''_r \end{aligned} \quad (3.53)$$

At the critical CAK-point we can use Eq. 3.52 to eliminate v''_r . This leads to the third condition:

$$\left(\frac{\partial A}{\partial r} + \frac{\partial A}{\partial v_r} v'_r \right) v'_r + \left(\frac{\partial B}{\partial r} + \frac{\partial B}{\partial v_r} v'_r \right) \bigg|_{r_c, v_{rc}} = \left(\frac{\partial C}{\partial r} + \frac{\partial C}{\partial v_r} v'_r \right) v'^{\alpha_{\text{cak}}} \quad (3.54)$$

The forth condition is not located at the critical point but at the base of the wind, where our solution should fit the conditions of the photosphere. We can specify the optical depth or the wind velocity there. The Eq. 3.39, 3.52 & 3.54 can be solved analytically for r_c , v_{rc} , and v'_{rc} . CAK solved for $\dot{M}$ instead of r_c . In any case we have to assume a value for the forth unknown, find the critical CAK-point, integrate Eq. 3.39, and finally improve our assumption about the forth unknown using the boundary condition at the base of the wind. This procedure converges sufficiently fast.

The CAK model gives us a simple description for the momentum transfer from the radiation to the wind. But this includes no description for the energy transfer between radiation and wind. Therefore it is not possible to solve simultaneously the energy equation for the local temperature. Instead we have to assume a temperature distribution before we can solve Eq. 3.39 for the velocity distribution. A separate model can then be used to improve the temperature distribution as CAK did [16, 14]. This iteration converges fast, because the velocity distribution depends only weakly on the temperature distribution.

When we ask for a wind solution with constant but nonzero temperature, we can apply our discussion about the critical CAK-point. So we would expect a unique solution. But if we write down the third critical point condition for w

$$\frac{\partial \bar{A}}{\partial w} \dot{w}^2 + \frac{\partial \bar{B}}{\partial u} = 0 \quad (3.55)$$

$$\frac{\partial \bar{A}}{\partial w} = \frac{v_s^2}{2w^2} > 0 \quad (3.56)$$

$$\frac{\partial \bar{B}}{\partial u} = 2v_s^2 > 0 \quad (3.57)$$

we see that $\dot{w}^2$ must be negative. This would lead to complex and therefore unphysical solutions for Eq. 3.44.

The basic theory, described here, had been improved in many ways. This includes the improved fit formula for the force multiplier by Abbott [2], the correction for the finite size of the star [19, 60], the inclusion of multiple photon scattering [38, 23], and the detailed line balance models of Kudritzki [32, 59]. But in this thesis we want to emphasize the effect of magnetic fields. Therefore we will restrict ourself to this basic formalism.

Chapter 4

Magnetic fields in stellar winds

4.1 Introduction

Already Parker [58] argued about the role of the magnetic field in the solar wind. But the solar magnetic field is weak. Its contribution to the momentum balance is small compared to the thermal pressure of the hot corona. Therefore he neglected the Lorentz force as we did in Chapter 2. But he saw the importance of the magnetic field for the angular momentum balance of the sun.

Weber & Davis [69] were the first who replaced the hydrodynamical treatment of Parker by a magnetohydrodynamic (MHD) treatment to analyze the importance of the magnetic field for the solar wind. The second important ingredient for their model was the rotation of the sun, which was neglected by Parker as well. Without rotation the material will stream out radially along radial, open field lines. In this case there will be no net force and we end up with the physics of Parker's model.

Biermann & Cassinelli [9, 8] developed an improved version of the Weber & Davis model, which treats the magnetic field in the equatorial plane without any further simplifications beyond the basic assumptions we made already as well. This allows for an oblique magnetic field at the stellar surface, which occurs in fast magnetic rotators. This model is the basis for our analysis of magnetic stellar winds. We present here the derivation in a generalized version. Biermann & Cassinelli and Weber & Davis assumed that meridional diameter of the fluxsheet is proportional to r . This leads e.g. to radial magnetic field proportional to r^{-2} . We introduce an arbitrary function $a(r)$, which allows us to describe the derivation from this r^{-2} law due to the influence of a wind compressed disk or a wind, which is diluted in the equatorial plane by a non-equatorial wind collimated towards the poles.

In Sect. 4.2 we derive our wind equations from the fundamental equations of magnetohydrodynamics. In Sect. 4.3 we discuss briefly simplified versions of our equations. And finally we discuss in Sect. 4.5 the spin-down problem, which gives limitations for the model parameters.

4.2 The model

We start our derivation from the magneto-hydrodynamical equations for an ideal, perfectly conducting gas in a stationary situation.

In the case of the Parker wind we had a perfect spherical symmetry, which reduced the problem directly to one spacial dimension. The one dimensional solution was valid for all areas in the wind. For a rotating star we have only one axis of symmetry. Therefore we can reduce our problem strictly only by one dimension. For a stellar wind it is most useful to introduce spherical coordinates parallel to the rotation axis and then to neglect the dependence of any physical quantity on the azimuthal angle ϕ . For winds from other objects (e.g. disks) a cylindrical coordinate system might be more useful. In any case we should solve the MHD equations in the two dimensions of the meridional plane. In this plane we can not expect more symmetry because the MHD equations mix the radial symmetry of gravitation and radiation with the cylindrical symmetry of the centrifugal force. A rigid two dimensional treatment is beyond the scope of this project. But we can reduce the problem to one dimension if we assume a priori a certain geometry of the flow in the meridional plane. This concept is called the fluxsheet approximation. We have to assume the path of the fluxsheet in the meridional plane and its cross section, varying along the fluxsheet. Then we need only to find the various physical quantities along the fluxsheet. This is a one dimensional problem. In this chapter we choose the equatorial plane as fluxsheet. From observation we know, that our sun has a wind in the equatorial plane. And the principal symmetry between northern and southern hemisphere of a star makes this scenario quite probable for other stars as well. The only

Figure 4.1: An equatorial fluxsheet in the (r, θ) plane. Fig. **A**) shows the situation in previous models. The thickness of the fluxsheet in the meridional plane is proportional to r . Due to the rotational symmetry the same is true in the equatorial plane. The cross section of the fluxsheet is therefore proportional to r^2 . Fig **B**) The dimensionless function $a(r)$ describes the deviation of the fluxsheet cross section from r^2 .

other reasonable configuration in the equatorial plane is an accretion disk. We will discuss non-equatorial winds in Chap. 7.

We start from the equations of magnetohydrodynamics (MHD) for a nonviscous, perfectly conducting, and quasi stationary gas:

$$\nabla \cdot (\rho \mathbf{v}) = 0 \quad (4.1)$$

$$\rho(\mathbf{v} \cdot \nabla) \mathbf{v} = \mathbf{F}_{\text{ext}} - \frac{1}{4\pi} \mathbf{B} \times (\nabla \times \mathbf{B}) \quad (4.2)$$

$$\nabla \times (\mathbf{v} \times \mathbf{B}) = 0. \quad (4.3)$$

The external forces

$$\mathbf{F}_{\text{ext}} = F_{\text{ext}} \mathbf{e}_r \quad (4.4)$$

$$= -\rho \nabla \Phi - \nabla P + \mathbf{F}_{\text{rad}} \quad (4.5)$$

include gravity, radiation pressure, and thermal pressure as discussed in the previous chapters. Since we restrict our discussion to the equatorial plane ($\theta = \pi/2$) we can set v_θ and B_θ to zero. But there derivatives with respect to θ might not be zero. The momentum equation then simplifies to

$$\rho \frac{v_r}{r} \frac{\partial r v_\phi}{\partial r} = \frac{1}{4\pi} [(\nabla \times \mathbf{B}) \times \mathbf{B}]_\phi = \frac{B_r}{4\pi r} \frac{\partial r B_\phi}{\partial r} \quad (4.6)$$

$$\left(v_r \frac{\partial v_r}{\partial r} \right) \left[1 - \frac{v_s^2}{v_r^2} \right] = -\frac{GM}{r^2} + \frac{v_s^2}{r} \left(2 + \frac{r}{a} \frac{\partial a}{\partial r} \right) - \frac{\partial v_s^2}{\partial r} + g_{\text{rad}} + \frac{v_\phi^2}{r} - \frac{1}{8\pi \rho r^2} \frac{\partial}{\partial r} (r B_\phi)^2. \quad (4.7)$$

In the fluxsheet concept the conservation laws for magnetic flux and matter are given by

$$F_B = B_r r^2 a(r) = \text{const} \quad (4.8)$$

$$\dot{M} = 4\pi \rho r^2 v_r a(r) = \text{const}. \quad (4.9)$$

The definition of $\dot{M}$ can be misleading. It is in analogy to the definition for a spherical wind, where we have $a(r) \equiv 1$. In the case of a cylindrical wind with rotation we must calculate the wind for all latitudes to get an accurate value for the total mass loss of the star. But if we assume that the wind is mostly spherical at the base of the wind ($r = R$), and if we normalize a to $a(R) = 1$, Eq. 4.9 will give a good estimate for the total mass loss rate. If we assume that the mass loss is reduced at the poles due to the missing rotation there, Eq. 4.9 will give an upper limit for the real mass loss rate. Which case is true, depends on the rotation rate of the star.

The flux freezing condition Eq. 4.3 for the perfectly conducting wind in the equatorial plane leads to

$$0 = \frac{\partial}{\partial r} [r(v_\phi B_r - v_r B_\phi)] - \frac{\partial}{\partial \theta} (v_\theta B_\phi - v_\phi B_\theta). \quad (4.10)$$

The symmetry between northern and southern hemisphere requires that all quantities except v_θ and B_θ have a vanishing derivative with respect to θ in the equatorial plane. Now we replace the θ -derivatives of v_θ and B_θ using $\nabla \cdot \mathbf{B} = 0$ and Eqs. 4.1, 4.8 & 4.9

$$0 = \frac{\partial}{\partial r} [r(v_\phi B_r - v_r B_\phi)] - \frac{a'}{a} (v_r B_\phi - v_\phi B_r), \quad (4.11)$$

where we used the $'$ to mark the derivative with respect to r . This equation can be directly integrated and leads to

$$ar(v_r B_\phi - v_\phi B_r) = \text{const} \quad (4.12)$$

$$= -\Omega a_0 R^2 B_{r0} \quad (4.13)$$

$$= -\Omega F_B. \quad (4.14)$$

Here we introduce the concept of the 'base of the wind'. At the base of the wind we have a negligible radial wind velocity. It is the transition region between the static envelope and the dynamically expanding wind of the star. We use R for the radius of the base of the wind and denote other physical quantities at the base of the wind with the index $_0$. For stars with a weak, optically thin wind, like our sun and most main sequence stars, the base of the wind is identical with the photosphere defined by an optical depth of one for electron scattering. This is e.g. not true for Wolf-Rayet stars. We denote the rotation rate of the star with Ω . It is defined by the rotation of the quasi stationary magnetic field configuration. At the base of the wind the radial velocity v_{r0} can be neglected compared to the co-rotation velocity $v_{\text{rot}0} = \Omega R$. If at the base of the wind the radial component B_{r0} and the azimuthal component $B_{\phi0}$ of the magnetic field are of the same order, the azimuthal component of the wind velocity v_ϕ will be nearly identical to the co-rotation velocity at the base of the wind. In this case Ω will be the rotation velocity of the stellar surface as well. We will later find this confirmed in our numerical models. It is important to note at this place, that Ω may depend on latitude. This is e.g. the case for our sun. From theoretical models we know as well, that the rotation rate can change drastically inside the star.

Due to the rotational symmetry of our star the angular momentum component parallel to the rotation axis is a conserved quantity. Equation 4.6 describes the transport of angular momentum in the wind. Using the conservation laws for magnetic flux and matter we can integrate Eq. 4.6 to yield the angular momentum loss of the star per unit wind mass

$$L_j = rv_\phi - \frac{B_r}{4\pi\rho v_r} r B_\phi = \text{const}. \quad (4.15)$$

This includes the angular momentum in the wind matter and the angular momentum in the bent magnetic field. We parametrize L_j by

$$L_j = \epsilon \Omega R^2, \quad (4.16)$$

where ΩR^2 is the angular momentum transport per unit mass by matter at the base of the wind. The angular momentum transport of the magnetic field at the base of the wind is included through the dimensionless factor ϵ . For all reasonable configurations ϵ is larger than 1. We discuss this later in detail.

The radial velocity can be expressed relative to the radial Alfvénic velocity by

$$M_{Ar} = \frac{v_r}{v_{Ar}} = \frac{v_r}{\frac{B_r}{\sqrt{4\pi\rho}}}. \quad (4.17)$$

This leads to

$$\frac{1}{M_{Ar}^2} = \frac{B_r^2}{4\pi\rho v_r^2} \frac{a^2 r^4}{a^2 r^4} = \frac{F_B^2}{M} \frac{1}{v_r a r^2} = \frac{1}{M_{Ar0}^2} \frac{v_{r0} a_0 R^2}{v_r a r^2} \quad (4.18)$$

and

$$\frac{1}{M_{Ar}^2} \frac{r^2}{R^2} \frac{1}{\epsilon} = \frac{F_B^2}{M} \frac{\Omega}{L_j v_r a} \quad (4.19)$$

$$= \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{1}{\epsilon} \frac{a_0}{a}. \quad (4.20)$$

With Eq. 4.14,4.15&4.19 we can now express v_ϕ by

$$v_\phi = \frac{L_j}{r} \frac{1 - \frac{F_B^2}{M} \frac{\Omega}{L_j v_r a}}{1 - \frac{F_B^2}{M} \frac{1}{v_r a r^2}} \quad (4.21)$$

$$= \frac{L_j}{r} \frac{1 - \frac{1}{M_{Ar}^2} \frac{r^2}{R^2} \frac{1}{\epsilon}}{1 - \frac{1}{M_{Ar}^2}} \quad (4.22)$$

$$= (\Omega r) \frac{U_M - U_\epsilon}{U_M}, \quad (4.23)$$

where we have introduced the auxiliary quantities

$$U_\epsilon = 1 - \epsilon \left(\frac{R}{r} \right)^2 \quad (4.24)$$

$$U_M = 1 - \frac{1}{M_{Ar}^2} \quad (4.25)$$

$$= 1 - \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \left(\frac{R}{r} \right)^2 \frac{a_0}{a}. \quad (4.26)$$

Now we have expressed v_ϕ in terms of r and v_r . Before we can solve Eq. 4.7 as an ordinary differential equation in $v_r(r)$ we have to do the same for

$$B_\phi = \frac{1}{v_r r} \left[r v_\phi B_r - \frac{\Omega F_B}{a} \right] \quad (4.27)$$

$$= -\frac{\Omega F_B}{v_r r} \frac{1}{U_M} \left[\frac{U_M}{a} - \frac{r B_r}{\Omega F_B} \frac{L_j}{r} \left(1 - \frac{F_B^2}{M} \frac{\Omega}{L_j v_r a} \right) \right] \quad (4.28)$$

$$= -\frac{\Omega F_B}{v_r r} \frac{1}{U_M} \frac{1}{a} \left[1 - \frac{L_j}{\Omega r^2} + \frac{F_B^2}{M v_r a} \left(\frac{1}{r^2} - \frac{1}{r^2} \right) \right] \quad (4.29)$$

$$= -\frac{\Omega F_B}{v_r r a} \frac{U_\epsilon}{U_M}. \quad (4.30)$$

The Lorentz force term in Eq. 4.7 can be split into two parts by

$$-\frac{1}{8\pi\rho r^2} \frac{\partial}{\partial r} (r B_\phi)^2 = -\frac{a v_r}{2\dot{M}} \frac{\partial}{\partial r} (r B_\phi)^2 \quad (4.31)$$

$$= \underbrace{-\frac{a}{v_r} \frac{\partial}{\partial r} \left(\frac{v_r^2}{2} \frac{(r B_\phi)^2}{\dot{M}} \right)}_{II} + \underbrace{\frac{a (r B_\phi)^2}{v_r \dot{M}} \left(v_r \frac{\partial v_r}{\partial r} \right)}_I. \quad (4.32)$$

Each part can now be expressed in terms of r , v_r , and v_r' .

$$I = \frac{a}{v_r \dot{M}} \left(\frac{\Omega F_B}{a v_r} \frac{U_\epsilon}{U_M} \right)^2 \quad (4.33)$$

$$= \left(\frac{\Omega r}{v_r} \right)^2 \frac{a_0}{a} \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{R^2}{r^2} \left(\frac{U_\epsilon}{U_M} \right)^2 \quad (4.34)$$

$$= \frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \left(\frac{U_\epsilon}{U_M} \right)^2 \quad (4.35)$$

$$II = -\frac{a \Omega^2 F_B^2}{2 \dot{M} v_r} \frac{\partial}{\partial r} \left(\frac{U_\epsilon}{a U_M} \right)^2 \quad (4.36)$$

$$= -\frac{a a_0}{M_{Ar0}^2} \left(\frac{\Omega R^2}{v_{r0}} \right)^2 \frac{v_{r0}^3}{v_r} \left(\frac{U_\epsilon}{a U_M} \right) \left(\frac{U_\epsilon' a U_M - U_\epsilon (a U_M)'}{a^2 U_M^2} \right) \quad (4.37)$$

$$= -\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R^2}{v_{r0}} \right)^2 \frac{v_{r0}^3}{v_r} \frac{U_\epsilon}{U_M^3} \left[2\epsilon \frac{R^2}{r^3} U_M - U_\epsilon \left(\frac{a'}{a} + \frac{2}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{R^2}{r^3} \frac{a_0}{a} \right) - U_\epsilon \frac{1}{M_{Ar0}^2} \frac{v_{r0} v_r'}{v_r^2} \frac{a_0}{a} \right] \quad (4.38)$$

$$= -\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R^2}{v_{r0}} \right)^2 \frac{v_{r0}}{v_r} \frac{v_{r0}^2}{r} \frac{U_\epsilon}{U_M^3} \left[2(1 - U_\epsilon) U_M - 2U_\epsilon(1 - U_M) - U_\epsilon \frac{ra'}{a} - U_\epsilon(1 - U_M) \frac{rv_r'}{v_r} \right] \quad (4.39)$$

$$= \frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R^2}{v_{r0}} \right)^2 \frac{v_{r0}}{v_r} \frac{v_{r0}^2}{r} \frac{U_\epsilon}{U_M^2} \left(2 \frac{U_\epsilon - U_M}{U_M} + \frac{U_\epsilon}{U_M} \frac{ra'}{a} \right) + \underbrace{\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R^2}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \frac{U_\epsilon^2}{U_M^3} (1 - U_M) \left(v_r \frac{\partial v_r}{\partial r} \right)}_{III} \quad (4.40)$$

Here we used again the ' to mark the derivative with respect to r . It useful to collect terms depending on v_r' , because this makes it later easier to find v_r' as function of r and v_r .

$$I + III = \frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \left(\frac{U_\epsilon}{U_M} \right)^2 \left[1 + \frac{1 - U_M}{U_M} \right] \quad (4.41)$$

$$= \frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \frac{U_\epsilon^2}{U_M^3} \quad (4.42)$$

As final result for the Lorentz force term we get then

$$-\frac{1}{8\pi\rho r^2} \frac{\partial}{\partial r} (rB_\phi)^2 = \quad (4.43)$$

$$\left(v_r \frac{\partial v_r}{\partial r} \right) \left[\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \frac{U_\epsilon^2}{U_M^3} \right] - \quad (4.44)$$

$$\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{v_{r0}}{v_r} \frac{v_{r0}^2}{r} \frac{U_\epsilon}{U_M^2} \left(2 \frac{U_M - U_\epsilon}{U_M} - \frac{U_\epsilon}{U_M} \frac{ra'}{a} \right). \quad (4.45)$$

This can now be combined with the term for the centrifugal force

$$\frac{v_\phi^2}{r} = \left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{v_{r0}^2}{R} \frac{r}{R} \left(\frac{U_M - U_\epsilon}{U_M} \right)^2 \quad (4.46)$$

to

$$\begin{aligned} \frac{v_\phi^2}{r} - \frac{1}{8\pi\rho r^2} \frac{\partial}{\partial r} (rB_\phi)^2 &= \left(v_r \frac{\partial v_r}{\partial r} \right) \left[\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \frac{U_\epsilon^2}{U_M^3} \right] + \\ &\left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{v_{r0}^2}{r} \frac{r^2}{R^2} \frac{U_M - U_\epsilon}{U_M^2} \left(U_M - U_\epsilon - \frac{2}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{R^2}{r^2} \frac{a_0}{a} \frac{U_\epsilon}{U_M} \right) + \\ &\frac{1}{M_{Ar0}^2} \frac{a_0}{a} \left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{v_{r0}}{v_r} \frac{v_{r0}^2}{r} \frac{U_\epsilon^2}{U_M^3} \frac{ra'}{a} \end{aligned} \quad (4.47)$$

$$\begin{aligned} &= \left(v_r \frac{\partial v_r}{\partial r} \right) \left[\frac{1}{M_{Ar0}^2} \left(\frac{\Omega R}{v_{r0}} \right)^2 \left(\frac{v_{r0}}{v_r} \right)^3 \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \right] - \\ &\left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{v_{r0}^2}{r} \frac{R^2}{r^2} \frac{1}{U_M^2} \left(\epsilon - \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{a_0}{a} \right) \left[\left(2 \frac{U_\epsilon}{U_M} + 1 \right) \frac{1}{M_{Ar0}} \frac{v_{r0}}{v_r} \frac{a_0}{a} - \epsilon \right] + \\ &\left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{v_{r0}^2}{r} \frac{U_\epsilon^2}{U_M^3} \frac{a_0 ra'}{a^2} \end{aligned} \quad (4.48)$$

Now we can write the radial momentum equation (Eq. 4.7) as an ordinary differential equation in $v_r(r)$, which allows the desired one dimensional solution:

$$\begin{aligned}
& -\frac{r^2}{GM} \left(v_r \frac{\partial v_r}{\partial r} \right) \left[1 - \frac{v_s^2}{v_r^2} - \frac{1}{M_{Ar0}^2} \left(\frac{v_{r0}}{v_r} \right)^3 \left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \right] = \\
& 1 - \frac{v_s^2 r}{GM} \left(2 + \frac{ra'}{a} \right) + \frac{r^2}{GM} \frac{\partial v_s^2}{\partial r} - \frac{r^2 g_{\text{rad}}}{GM} + \\
& \frac{\Omega^2 R^3}{GM} \frac{R}{r} \frac{1}{U_M^2} \left(\epsilon - \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{a_0}{a} \right) \left[\left(2 \frac{U_\epsilon}{U_M} + 1 \right) \frac{1}{M_{Ar0}} \frac{v_{r0}}{v_r} \frac{a_0}{a} - \epsilon \right] - \\
& \frac{\Omega^2 R^3}{GM} \frac{r}{R} \frac{1}{M_{Ar0}^2} \frac{v_{r0}}{v_r} \frac{U_\epsilon^2}{U_M^3} \frac{a_0 r a'}{a^2}
\end{aligned} \tag{4.49}$$

In this chapter we neglect the radiative acceleration although we included the radiation term for reference into Eq. 4.49. Here we want to concentrate on the effect of the magnetic field. The CAK model for the line acceleration acceleration introduces a radiative term which is nonlinear in v_r' . We discuss the consequences of such a term in the next chapter.

For the numerical solution of this equation we introduce dimensionless variables

$$y = \frac{v_r}{v_*} \tag{4.50}$$

$$u = \frac{r_*}{r} \tag{4.51}$$

$$GM = r_* v_*^2. \tag{4.52}$$

Using $u \sim r^{-1}$ instead of $u \sim r$ has the advantage that the region close to the stellar surface, where the wind is strongly accelerated on a short length scale is enlarged. This region is the interesting region, where most things happen. the enlargement in the u -scale will ensure proper solutions for the wind equation in this region. On the other side we have the region far away from the star, where the wind is streaming outward with a nearly constant velocity. This region is physically and numerically uninteresting. In the u -scale this region is shrunk. And therefore not much numerical effort will be spent to solve the wind equation there. With a proper temperature stratification this region can even extend to $r = \infty$ ($u = 0$). Chap. 5 shows several plots with wind solutions as functions of u , which show nicely that u is the appropriate coordinate to compute and to plot wind solutions up to large radii. Our choice for the length and velocity scale has still one degree of freedom. We can still choose an arbitrary value for r_* or v_* . This of course has no influence on the physics. But an improper choice can trouble the numerics. One good choice for fast magnetic rotator models (strong magnetic field, fast rotation) is the Michel velocity

$$v_M = \frac{v_{r0}}{M_{Ar0}^{2/3}} \left(\frac{\Omega R}{v_{r0}} \right)^{2/3}. \tag{4.53}$$

We choose for simplicity just the stellar radius as length scale

$$r_* = R. \tag{4.54}$$

This length scale is reasonable for all wind models – even for nonrotating or nonmagnetic wind models. The dimensionless version of Eq. 4.49 is

$$\begin{aligned}
& y y' \left[1 - \frac{y_s^2}{y^2} - \frac{y_{\text{rot}0}^2}{y^2} \frac{Q}{y} \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \right] = \\
& 1 - \frac{y_s^2}{u} \left(2 - \frac{u \dot{a}}{a} \right) - \frac{\partial y_s^2}{\partial u} - \frac{a_{\text{rad}}}{u^2} + \\
& \frac{\lambda}{U_M^2} \frac{u}{u_0} \left[\epsilon - \frac{Q}{y} \frac{a_0}{a} \right] \left[\left(2 \frac{U_\epsilon}{U_M} + 1 \right) \frac{Q}{y} \frac{a_0}{a} - \epsilon \right] + \\
& \frac{\lambda}{U_M^2} \frac{u_0}{u} \frac{U_\epsilon^2}{U_M} \frac{Q}{y} \frac{a_0 u \dot{a}}{a^2},
\end{aligned} \tag{4.55}$$

where we have used the dimensionless quantities:

$$a_{\text{rad}} = \frac{r_*^2 g_{\text{rad}}}{GM} \tag{4.56}$$

$$\lambda = \frac{\Omega^2 R^3}{GM} \quad (4.57)$$

$$y_{\text{rot}0} = \frac{\Omega R}{v_*} \quad (4.58)$$

$$Q = \frac{y_0}{M_{\text{Ar}0}^2} \quad (4.59)$$

$$y_s = \frac{v_s}{v_*} \quad (4.60)$$

$$\dot{a} = \frac{\partial a}{\partial u} \quad (4.61)$$

$$\dot{y} = \frac{\partial y}{\partial u} \quad (4.62)$$

In analogy to Eq. 3.39 we can write Eq. 4.55 as

$$A(u, y)\dot{y} + B(u, y) = 0. \quad (4.63)$$

Equation 4.55 is the fluxsheet generalization of the results of Biermann & Cassinelli [9] and Biermann [8].

4.3 Simplified versions

For this model it is important that both, magnetic field and rotation, are present. If we would turn the rotation off ($\lambda = y_{\text{rot}0} = 0$) Eq. 4.49 directly simplifies to the equation of the Parker wind. The open magnetic field lines would be stretched out radially by the wind.

If we take rotation into account but assume that the star has no relevant magnetic field, the conservation of angular momentum (Eq. 4.15) would simplify to

$$rv_\phi = \text{const} \quad \Rightarrow \quad v_\phi = \frac{v_{\phi 0} R}{r} = \frac{\Omega R^2}{r}. \quad (4.64)$$

For Eq. 4.55 we find then

$$y\dot{y} \left[1 - \frac{y_s^2}{y^2} \right] = 1 - \frac{y_s^2}{u} \left(2 - \frac{u\dot{a}}{a} \right) - \frac{\partial y^2}{\partial u} - \frac{a_{\text{rad}}}{u^2} + \lambda \frac{u}{u_0}. \quad (4.65)$$

This scenario in combination with a CAK radiation force has been analyzed by Pauldrach et al. [60].

4.4 The critical points

As in the case of the Parker or CAK wind it is important to understand the critical points of Eq. 4.55 to find proper physical solutions. In this model we have not one but three critical points. Under certain circumstances the solution need not pass through all these points. But nevertheless it is important to understand them all.

The most important critical point is the Alfvénic point. At this point with $r = r_{\text{Ac}}$ the radial wind velocity equals the radial Alfvénic velocity ($M_{\text{Ar}} = 1$). And therefore U_M will be zero at this point and change its sign. If we require that B_ϕ is finite and continuous, U_ϵ must be zero and change its sign there as well (Eq. 4.30). For the radius of the Alfvénic point and the radial velocity there we find

$$u_{\text{Ac}} = \frac{u_0}{\sqrt{\epsilon}} \quad (4.66)$$

$$y_{\text{Ac}} = \frac{Q}{\epsilon}. \quad (4.67)$$

As in Chap. 2 we can try to use l'Hospital's rule again to find $\dot{y}$ at the critical point:

$$\left. \frac{U_\epsilon}{U_M} \right|_{r=r_{\text{Ac}}} = \left. \frac{\dot{U}_\epsilon}{\dot{U}_M} \right|_{u=u_{\text{Ac}}} = \left. \frac{\frac{\dot{a}}{a} - \frac{2}{u}}{\frac{\dot{a}}{a} + \dot{y} - \frac{2}{u}} \right|_{u=u_{\text{Ac}}} \quad (4.68)$$

In the case of the Weber & Davis wind we do not find a finite number of possible values for $\dot{y}_{\text{Ac}}$. Therefore we do not have a simple X-type critical point here like in the Parker wind. This local analysis allows a range of values for $\dot{y}_{\text{Ac}}$. We find in general

$$\frac{U_\epsilon}{U_M} = -\frac{B_\phi}{B_r} \frac{v_r}{\Omega r}. \quad (4.69)$$

Depending of the values of v_r and $\mathbf{B}$, U_ϵ/U_M can have different values. This leads to different values for $\dot{y}_{Ac}$ according to Eq. 4.68.

Since U_ϵ/U_M is finite, and U_M equals 0, at r_{Ac} the U_ϵ^2/U_M^3 term in $A(u, y)$ will dominate for $r \approx r_{Ac}$. For $r \lesssim r_{Ac}$ we have $A > 0$. But if the velocity at the base of the wind is small enough, $A(u_0, y_0)$ will be less than zero due to the then dominating thermal pressure term. For $r \gtrsim r_{Ac}$ we have $A < 0$. And for sufficient high velocities at $r = \infty$ A will be positive due to the inertia term. So we have two radii $R < r_s < r_{Ac}$ and $r_{Ac} < r_f < \infty$ where A will be zero. At these radii we have a X-type singularity as in the Parker wind. We denote these critical points and their analogies in the case of an magnetic CAK wind as the inner and the outer critical points. The condition $A = 0$ leads to

$$0 = v_r - \frac{v_s^2}{v_r} - \frac{v_r}{M_{Ar0}^2} \left(\frac{v_{r0}}{v_r} \right)^3 \left(\frac{\Omega R}{v_{r0}} \right)^2 \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \quad (4.70)$$

$$= v_r - \frac{v_s^2}{v_r} - \frac{B_\phi^2}{4\pi\rho v_r} \frac{1}{U_M} \quad (4.71)$$

$$= U_M \left(1 - \frac{v_s^2}{v_r^2} \right) - \left(\frac{v_A^2}{v_r^2} - \frac{v_{Ar}^2}{v_r^2} \right) \quad (4.72)$$

$$= v_r^4 - (v_A^2 + v_s^2)v_r^2 + v_s^2 v_{Ar}^2, \quad (4.73)$$

where we have used the total Alfvénic velocity

$$v_A = \frac{B_r^2 + B_\phi^2}{4\pi\rho}. \quad (4.74)$$

Equation 4.73 is the well known dispersion relation for slow and fast magnetosonic waves [27]. Therefore at the slow and fast critical point the radial wind velocity v_r equals the local phase velocity for slow respectively fast magnetosonic waves. There is a deep physical connection to the problem of causality in a stationary physical model. Weber & Davis [69, Figs. 1&2] described the topology for the solution Eq. 4.63 and the role of the critical points. In the next chapter we combine the Weber & Davis model in the form presented here with the CAK model. There we will discuss the critical points and the solution topology in detail.

4.5 The spin-down problem

One important aspect in the theory of magnetic winds is the angular momentum balance. Every star which rotates and loses mass will lose angular momentum as well, because the rotating surface layer of the star carries a certain fraction of the stellar angular momentum. When this layer evaporates into the wind it will take its angular momentum along. Due to a magnetic field or viscosity the angular momentum loss may be enhanced. We expressed this by the factor ϵ in our formula for the angular momentum loss per unit mass (Eq. 4.16). A normal star without an enhanced angular momentum loss has $\epsilon = 1$. The angular momentum loss rate¹ of a star is

$$\dot{L} = \int L_j \frac{\partial \dot{M}}{\partial \omega} d\omega, \quad (4.75)$$

where L_j is the angular momentum loss per unit mass (Eq. 4.15) and ω is the solid angle. In order to evaluate Eq. 4.75 properly we would have to calculate a whole 3-dimensional wind model. This is beyond this thesis. So we have to assume the star is sufficiently spherically symmetric at its surface, so that we can use the results from our equatorial wind model. This assumption is only good if the rotation rate is sufficiently low. Since this is not the case for most of our models, the results of this section should only be used carefully as a rough estimate. We find under these assumptions from Eq. 4.75

$$\dot{L} = \frac{2}{3}\epsilon \dot{M} R^2 \Omega = \frac{2}{3}\dot{M} r_{Ac}^2 \Omega. \quad (4.76)$$

The interesting point now is to compare the timescales for mass loss

$$\tau_M = \frac{M}{\dot{M}} \quad (4.77)$$

and angular momentum loss

$$\tau_L = \frac{L}{\dot{L}}. \quad (4.78)$$

¹ $\dot{L} = \partial L / \partial t$ is beside $\dot{M}$ the second exception from the rule that the dot marks a derivative with respect to u .

Figure 4.2: shows the magnetic field configuration in the equatorial plane of wind models with $\epsilon > 1$ (A) and $\epsilon < 1$ (B).

We know from observation and stellar evolution models that massive stars lose a large fraction of their mass before they explode as a supernova. I.e. their mass loss timescale is comparable to their lifetime. If rotation plays an important role through the whole life of a massive star, its angular momentum loss timescale should not be much smaller. Otherwise the star will spin-down already in an early stage of its evolution. The problem now is to estimate L , the total angular momentum of our star. Today no models for the inner structure of rapidly rotating stars with significant magnetic fields are available. The most simple but extremely unphysical assumption is a rigidly (!) rotating star of constant (!) density. In this case we have $L = (5/2)MR^2\Omega$ and therefore

$$\tau_L = \frac{3}{5} \frac{\tau_M}{\epsilon}. \quad (4.79)$$

This result suggests that every star has an angular momentum loss timescale smaller than the mass loss timescale. The naive interpretation would be that even a star without magnetic field ($\epsilon = 1$) would spin down rapidly. But of course, a star without angular momentum transport between different layers of material will not spin down at all, if we assume that it does not expand or shrink. If the angular momentum is conserved in every layer then every layer will keep to overall rotation rate. Due to all the simplifications Eq. 4.79 allows to criticize wind models only if τ_M and τ_L differ by more than one or two orders of magnitude. A final answer for the spin-down problem requires a unified model which describes the evolution of the star and its wind for all latitudes in detail over the whole lifetime. This is beyond today's possibilities.

Therefore our wind models are reasonable as long as they have a small value of ϵ . But what is the physical meaning of ϵ ? It is the factor by which the angular momentum loss is enhanced compared with the case of no magnetic field. From our discussion in the previous section we see that the radius of the Alfvénic point is given by $r_{Ac}^2 = \epsilon R^2$. If we make the quite physical assumption that the magnetic field transports angular momentum from the star away, we will always have $\epsilon > 1$ and therefore $r_{Ac} > R$. A star with ϵ less than 1 would lose less angular momentum than a star without magnetic field. If we assume that at the stellar surface (or somewhere just below) we have a layer of stellar material without significant outward motion ($v_r = 0$), we will have strict co-rotation there due to the flux freezing. When this layer evaporates into the wind, the magnetic field would have to transport angular momentum back into the star to keep the angular momentum loss less than in the case of a nonmagnetic star. Since the nonmagnetic star rotates with a constant rotation rate, a magnetic star with ϵ less than 1 would spin up like a rotating firework. Figure 4.2 shows the magnetic field configuration in the equatorial plane of wind models with $\epsilon > 1$ (A) and $\epsilon < 1$ (B). In the first case (A) the magnetic field line pushes the wind material outside and in the direction of the rotation. The first effect enhances the wind outflow. The second effect transfers extra angular momentum from the magnetic field to the wind matter. This extra angular momentum comes via the curvature of the field line from the star. In the second case the magnetic field line is mostly tangential at the stellar surface. The wind accelerated by radiation pressure pushes against the field line.

This bends the field line clockwise. Through this curvature angular momentum is transferred from the wind material via the field line back to the star. Therefore we have ϵ less than 1. The consequence of the curved field line is a Lorentz force which decelerates the wind in radial and azimuthal direction. If this effect is very strong the wind can even start to rotate counterclockwise. In any case scenarios of type B have a decelerating Lorentz force close to the stellar surface. The force balance close to the surface fixes the mass loss rate. Therefore wind models of type B will have a lower mass loss rate than the corresponding model without magnetic field. It is not even clear whether a configuration of type B is stable, because the field line has to be bent clockwise inside the star (dotted line in Fig. 4.2.B). Otherwise it would hit the clockwise bent stellar surface again. This would violate our assumption of rotational symmetry. We therefore conclude that ϵ must be larger than 1 in physical wind models with magnetic fields. And we will restrict our further analysis to that case.

Chapter 5

Magnetic CAK-winds

5.1 Introduction

In this chapter we discuss various numerical solutions for the equatorial wind model developed in the previous chapters. Where possible we compare our results with the literature. The combined wind equation for line driven winds with magnetic fields is

$$A(u, y)\dot{y} + B(u, y) = C(u, y)\dot{y}^{\alpha_{\text{cak}}}. \quad (5.1)$$

We know this form of the wind equation already from our discussion of nonmagnetic, line driven winds in Chap. 3 (Eq. 3.39). But now we use the dimensionless quantities (Eqs. 4.50–4.52) and extend the coefficients A and B by the magnetic terms derived in Chap. 4 (Eq. 4.55):

$$A(u, y) = y \left[1 - \frac{y_s^2}{y^2} - \frac{y_{\text{rot0}}^2}{y^2} \frac{Q}{y} \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \right] \quad (5.2)$$

$$B(u, y) = 1 - \Gamma - \frac{y_s^2}{u} \left(2 - \frac{u\dot{a}}{a} \right) - \frac{\partial y_s^2}{\partial u} + \frac{\lambda}{U_M^2} \frac{u}{u_0} \left[\epsilon - \frac{Q}{y} \frac{a_0}{a} \right] \left[\left(2 \frac{U_\epsilon}{U_M} + 1 \right) \frac{Q}{y} \frac{a_0}{a} - \epsilon \right] + \frac{\lambda}{U_M^2} \frac{u_0}{u} \frac{U_\epsilon^2}{U_M} \frac{Q}{y} \frac{a_0 u \dot{a}}{a^2} \quad (5.3)$$

$$C(u, y) = \Gamma k_{\text{cak}} \left(\frac{4\pi G M}{\kappa_{\text{Th}} \dot{M} v_{\text{th}}} a y \right)^{\alpha_{\text{cak}}}. \quad (5.4)$$

Eq. 5.4 distinguishes from Eq. 3.43 beside the overall factor r^2/GM by the geometry factor $a(u)^{\alpha_{\text{cak}}}$. This factor comes from the equation of continuity, which we used between Eq. 3.42 and Eq. 3.43. The geometry factor $a(u)$ was not introduced before chapter 4.

A solution of this wind equation can pass through up to three critical points. In Sec. 4.4 we discussed the three critical points of a magnetic wind without line acceleration (i.e. $C = 0$). The Alfvénic critical point, we discussed there, exists in a line driven, magnetic wind as well. And our arguments, that A will pass through zero somewhere inside and outside the Alfvénic point, are still valid. But since we have now the line driving term $C\dot{y}^{\alpha_{\text{cak}}}$ in our Eq. 5.1, we can not use the old Parker argument that $A(u, y) = 0$ implies $B(u, y) = 0$. Therefore we do not have the classical X-type critical point at the radii where $A(u, y)$ is zero. Rather A and B change their signs in the subtle way we described for the critical point of nonmagnetic CAK-wind in Sec. 3.4. So we have two critical points of the CAK-type.

In order to compute a numerical model we have to fix several model parameters. The star is described by its mass M , its luminosity L , its radius R , its rotation rate Ω , and its surface radial magnetic field strength B_{r0} . For the wind we have to specify the CAK-parameters α_{cak} and k_{cak} , the temperature profile $T(r)$, the electron scattering opacity κ_{Th} , and the meridional shape of the wind described here by the area function $a(r)$. When we put all these numbers into Eqs. 5.1–5.4 we find that two further quantities remain to be fixed. E.g. we can specify additionally the mass loss rate $\dot{M}$ and the radius of the Alfvénic point r_{Ac} . These two parameters are very crucial because they allow to relate our numerical models to observation and to control the stellar angular momentum loss (Eq. 4.76), which is important for the stellar evolution. Therefore it would be nice, if these parameters were rather results than input parameters of our models. This can be realized, if we require that our wind solution has to pass through all three critical points. Through this additional assumption $\dot{M}$ and r_{Ac} become eigenvalues of our wind equation. We find these eigenvalues using the shooting method. For given values

of $\dot{M}$ and r_{Ac} we can find the two CAK-type points by solving twice the nonlinear set of equations 5.1, 3.52 & 3.54. From these points we can integrate Eq. 5.1 to the Alfvénic point (Eqs. 4.66 & 4.67), to the stellar surface, and to infinity. In Sec. 4.4 we argued that the acceleration $\dot{y}$ is not fixed a priori at the Alfvénic critical point. But, of course, $\dot{y}$ should be continuous at the Alfvénic point. Therefore we should find the same value of $\dot{y}(u_{Ac})$ when we integrate Eq. 5.1 from the inner and from the outer CAK-point to the Alfvénic point. This is the first condition for the eigenvalues $\dot{M}$ and r_{Ac} . The second condition is related to the stellar surface. We defined a stellar radius R as the radius at the base of the wind. In our models we require a certain, small, initial wind velocity y_0 at this radius. This condition is very reasonable from the theoretical point of view, because a theoretical wind model should describe, how the wind material is accelerated from the low, subsonic velocity of the quasi static, stellar atmosphere to the high observed terminal velocities. Alternatively we could require a certain optical depth (e.g. $\tau_0 = 1$) at the stellar radius R . For stars with an optical thin wind like O and B stars these two alternative definitions of R are practical identical. For stars with an optical thick wind like Wolf-Rayet stars the optical depth at the subsonic base of the wind is not known. If we would start our wind model for a Wolf-Rayet star at $\tau = 1$, we would describe only the outer, high velocity part of the wind. Such a model could not be considered as a complete wind model. Additionally specifying τ_0 requires more numerical effort than specifying y_0 . Therefore we prefer to specify y_0 .

In Sec. 5.2 we compare our results with the model of Friend & MacGregor [20], who published a model with a different wind equation. In Sec. 5.3 we our model to the case of only two critical points. This is important for our study of winds outside the equatorial plane in Chap. 7.

5.2 The wind models of Friend & MacGregor revisited

We start our discussion with wind models which have no compression or expansion of the wind in meridional direction, i.e. the cross section function $a(r)$ as defined in Eqs. 4.8 & 4.9 is constant. Additionally we assume that the wind passes through all three critical points. Such a model can be compared to the model published by Friend & MacGregor [20]. Their model is based on the CAK model for the radiative acceleration and the Weber Davis model for the magnetic acceleration (their Eqs. 1–21). Up to this point their model is identical with our model. But from these equations they derive a final differential equation for v_r (their Eqs. 22–26) which differs in the magnetic terms from our final equation (Eqs. 5.1–5.4). And this is not only a question of different notation. Our final equation is derived strictly from the common basic assumptions (their Eqs. 1–21) without any further assumptions or approximations. Due to the necessary brevity in an article Friend & MacGregor give no further information how they obtain their final equation from the basic equations. Therefore we can not analyze the differences between the final equation of Friend & MacGregor and our final equation in further details. To study the differences of our models in the numerical level we recalculated their numerical models with our software using our final wind equation. They calculated 16 models with varying magnetic field and rotation rate for the O6ef star λ Cephei. For this star they used the parameters: $M = 50M_\odot$, $L = 6.76 \times 10^5 L_\odot$, $R = 19.7R_\odot$. The sound speed $v_s = 30$ km/s is constant in the wind. This leads to a wind temperature of about 65000 K. For the radiative acceleration they claim to use the original CAK [16] values $\alpha_{cak} = 0.7$ and $k_{cak} = 1/30$. From the statement that the CAK terminal velocity (their Eq. 30, our Eq. 3.51) is 1240 km/s we can derive a value of $\Gamma = 0.319$ for the Eddington factor. Therefore we find for the electron scattering opacity per unit mass $\kappa_{Th} = 0.309$ cm²/g (called σ_e by Friend & MacGregor). For the CAK mass loss rate (their Eq. 31, our Eq. 3.50) they quote a value of $5.2 \times 10^{-6} M_\odot/\text{yr}$. For their parameters we find a value of $9.74 \times 10^{-7} M_\odot/\text{yr}$. We find the same discrepancy in the mass loss rates of the numerical models. We can fix this by assuming a modified CAK parameter $k_{cak} = 0.107$ instead of $k_{cak} = 1/30$. Finally we can deduce from their Tab. 2.B that their reference radius for the terminal velocity of their numerical models is 200 times the Alfvénic radius. For all numerical models we state the rotation rate in units of the critical rotation rate

$$\alpha_{rot} = \frac{v_{rot}}{v_{rot,crit}} = \frac{\Omega}{\Omega_{crit}} = \frac{\Omega R}{\sqrt{\frac{GM}{R}(1-\Gamma)}}. \quad (5.5)$$

α_{rot} gives a good intuitive feeling, whether the star rotates fast or slow. In the case $\alpha_{rot} = 1$ the centrifugal and radiative (Thompson scattering) forces will compensate gravity at the equator. An eruptive mass loss would be the consequence. This case is called the Ω -limit by Langer & Heger [34]. They claim that stars can really reach this limit.

In Table 5.1 we display analogously to Friend & MacGregor’s Tab. 1 our results for the 16 wind models extended by our values for the wind efficiency and the ratio between terminal velocity and the total Alfvénic velocity. We find larger differences only for the radius of the slow ($\approx 7\%$) and fast ($\approx 20\%$) critical points. In the first case this is due to our slightly different inner boundary condition. We require a fixed radial velocity ($v_{r0} = v_s/20$) at the photosphere. Friend & MacGregor required an optical depth for electron scattering of

Table 5.1: Wind models for λ Cephei analogous to the models of Friend & MacGregor [20].

$\tau_{\text{es}} = 1$ at the base of the wind. In the second case the differences are due to the bad numerical conditioning for finding the far critical point. All other values in Tab. 5.1 differ less than 3% between Friend & MacGregor's and our calculations. This difference is too small to distinguish any physical from numerical effects. Therefore we have to conclude that we found the same wind solutions as Friend & MacGregor although we used a different wind equation. Their additional assumptions or simplifications, which lead to their Eqs. 22–26, appear to be well chosen. For a deeper physical interpretation of these results we refer the reader to the paper of Friend & MacGregor, since we do not want to reprint all their arguments here in detail. In order to check our inner boundary condition we calculated models with different values of v_{r0} up to $3v_s$. We found that this has only a very small influence on the wind models. The model parameter like $\dot{M}$ and v_{∞} changed not more than 10%. This shows that our boundary condition at the base of the wind is not critical for our results. For most models they changed only a few percent. This weak dependence on the inner boundary condition explains also why we got the same results as Friend and MacGregor although they use a completely different inner boundary condition. Figs. 5.1–5.4 show the velocity profiles for four of our models plotted as function of R/r (the white curve). These figures show the different regions in the $(u = R/r, v_r)$ plane, which have zero, one, or two solutions for Eq. 5.1. The position of the three critical points are marked by white points. Tracing the solution from the stellar surface ($R/r = 1$) to infinity ($R/r = 0$) we can see how $A(u, y)$ and $B(u, y)$ evolve through the wind and why the solution has to pass through the two CAK-type critical points, if we require, that the wind starts at a subsonic velocity and extends to arbitrary large radii.

The interesting point in this section is that the approximations made by Friend & MacGregor leading to their version of the wind equation seems to be quite appropriate. It is not clear whether this is still true in the case of higher rotation rates. We will use higher rotation rates in Chap. 7 for our non-equatorial models.

5.3 Models with only two critical points

When we look at Fig. 5.5 we see that the region where Eq. 5.1 has two solutions extends down to the stellar surface – but only with a supersonic wind velocity. In Sec. 4.4 we argued that the wind has to pass through the inner critical point, because only if we switch the solution branch at the inner critical point the solution can extend into the subsonic part. But it is not clear whether our wind equation is still valid in the subsonic regime. Effects like turbulence, optical thickness, pulsation, meridional motions or other might dominate the wind there. In this case we might get wrong results if we try to describe the wind down to the subsonic regime with our model. Nevertheless if we restrict our calculations to the supersonic regime we still have to start close to the star with a wind velocity small compared to the terminal velocity. Otherwise our model is irrelevant because it does not answer the fundamental questions of wind physics: (1) How does the wind material escape from the gravity of the star? And (2) how is it accelerated to the high observed terminal velocities?

To analyze this question we modified our program, so that the wind solutions pass only through the outer

Figure 5.1: shows the radial wind velocity v_r (white curve) as function of $u = R/r$ for our version of Friend & MacGregor’s model 1 (weak $\mathbf{B}$ field & slow rotation). The three critical points (from left to right: the outer, the Alfvénic, and the inner critical point) are marked by white dots. Additionally we plot, using different gray scales, for every point in the (u, v_r) plane the local solution logic for Eq. 5.1, which is the magnetic version of Eq. 3.39. The “local solution logic” is explained for the nonmagnetic case in Sect. 3.4 and Fig. 3.1. The different cases in Fig. 3.1 are connected to the different grayscales in this plot by the legend on the right hand side. In the magnetic case we have two critical points of the (nonmagnetic) CAK-type: The inner and outer critical points. At the Alfvénic point Fig. 3.1.F applies. The wind solution shown in this plot passes from the stellar surface ($u = 1$) to infinity ($u = 0$) through the following sequence (c.f. Fig 3.1: C–E–A–B(here is the inner critical point)–A–D–F(here is the Alfvénic critical point)–C–A–B(here is the outer critical point)–A–D. The situation around the Alfvénic point can be seen better in Fig. 5.3.

and the Alfvénic critical points. Through this step we lose one of our conditions for the eigenvalues of Eq. 5.1. Now we have to specify either the acceleration at the Alfvénic point or the wind velocity at the stellar surface in order to integrate Eq. 5.1 between the stellar surface and the Alfvénic point. Therefore we do not find a unique solution any more. Rather we find a set of solutions with $\dot{M}$ as a function of r_{Ac} or vice versa.

We calculated solutions for the four corner models of Friend & MacGregor (models 1,4,13,16). Hereby we used an initial wind velocity at the stellar surface of $v_{r0} = 1.3 v_s = 39 \text{ km/s}$. In Tab. 5.2 we list for the four models the solutions with the smallest and the largest radius of the Alfvénic point (r_{Ac}). As reference level for the terminal velocity v_∞ we chose $100R$. This allows us to compare these results with the models in the next paragraph. For the models 1,4&13 we find that the Alfvénic radius r_{Ac} is reduced compared to the models with 3 critical points. But for model 16 we find only solutions with an enlarged Alfvénic radius. All other quantities vary up to an factor of two. This shows that even for fixed magnetic field strength and rotation rate magnetic wind models have a strong capability to fit observational constraints. Additionally we see that a proper treatment of the wind physics at the stellar surface is crucial for quantitative wind models. We did not expect this in the last section where we found that models with 3 critical points are insensitive for the initial wind velocity v_{r0} . Therefore it is important to improve the wind physics near to the stellar surface. Figure 5.7 shows our wind solution 13a. The interesting aspect about solution 13a is that it has a significantly reduced angular momentum loss ($\epsilon = 2$) compared to the model with 3 critical points no. 13 ($\epsilon = 3$). Additionally model 13a has a much steeper velocity law and a much higher terminal velocity than model 13. This can also help to fit observations. In Fig. 5.7 we show the velocity profile for our wind model 13a.

It is also possible to question whether the outer critical point exists. It will certainly exists when we have a finite temperature at an sufficiently large radius. But it is not necessary that our wind solution extends to infinity in the mathematical sense. This would not be physical as we discussed in Chap. 2. We can see in Fig. 5.6 that the wind solution has to pass through the outer critical point before it reaches at $r \approx 200R$ a region, where again only local solution of Eq. 5.1 exists. This was the argument which required the outer critical point. But we will discuss in the next chapter a model for linear waves in magnetic stellar winds. We will find there, that these waves are highly instable and will grow to linear shocks rapidly. Although the latter effect demands for a numerical model for nonlinear waves, we can seriously expect that the wind at large radii will

Figure 5.2: shows the same as Fig. 5.1 but for our version of Friend & MacGregor's model 4 (Strong $\mathbf{B}$ field & slow rotation). For the technical explanation of this plot check Fig. 5.1.

Figure 5.3: shows the same as Fig. 5.1 but for our version of Friend & MacGregor's model 13 (weak $\mathbf{B}$ field & fast rotation). For the technical explanation of this plot check Fig. 5.1.

Figure 5.4: shows the same as Fig. 5.1 but for our version of Friend & MacGregor's model 16 (Strong $\mathbf{B}$ field & fast rotation). For the technical explanation of this plot check Fig. 5.1.

Figure 5.5: shows the inner part of our wind model 16 (Fig. 5.4). The region with two solutions extends down to the stellar surface at $u = 1$. The wind solution can only extend into the subsonic part, after it has passed through the inner critical point. For the technical explanation of this plot check Fig. 5.1.

Figure 5.6: shows the outer part of our wind model 16 (Fig. 5.4). The wind solution can only extend beyond $u \approx 0.05$ ($r \approx 200R$) after it has passed through the outer critical point. For the technical explanation of this plot check Fig. 5.1.

not be a continuous, smooth, stationary flow, as assumed in the wind model used in this chapter, but rather a chaotic system of shocks and nonlinear waves. Therefore it might be that the smooth wind model used in this chapter is not a proper description for the stellar wind at large radii – even for the time averaged properties of the wind. If we restrict our wind model to smaller radii with $r < 200R$, the need for the outer critical point is relieved. Therefore we calculate now a set of wind models which have an inner but no outer critical point. As in the previous case we have therefore one free parameter in the model. Analogous to Tab. 5.2 Tab. 5.3 shows our results for wind models without an outer critical point. Hereby we restricted ourself to a maximum of $15R$ for the radius of the Alfvénic critical point r_{Ac} . Especially for wind model 13 such a high value for r_{Ac} is already unphysical. Figure 5.8 shows the extreme case of solution 13c. The wind solution starts at the stellar surface well above the region of no wind solution. Since our solutions pass through the inner critical point, we could have chosen a subsonic wind velocity at the stellar surface. But in order to compare these solutions with our solutions from the last paragraph we chose the same initial wind velocity of $v_{r0} = 39 \text{ km/s}$. Our solutions pass through the inner and the Alfvénic critical point, and stops at 100 stellar radii. This is well below the region where the passage through the outer critical point becomes important ($r \approx 300R$).

Since a picture can tell more than 1000 words we show finally for our wind model 13 the mass loss rate $\dot{M}$ vs. the terminal velocity v_{∞} (Fig. 5.9) and the wind efficiency $(\dot{M} v_{\infty})/(L/c)$ vs. the angular momentum enhancement factor ϵ (Fig. 5.10). The wind model with three critical points seems to form a situation between the two cases with only two critical points. From the view point of avoiding the spin-down problem in a strong wind models without an inner critical point are very interesting. They allow an increased wind efficiency together with a reduced angular momentum loss. This was made possible by the fact that we modified our model close to the

Figure 5.7: shows our wind model 13b. This solution has no inner critical point. Therefore the sequence of the solution logic from the stellar surface ($u = 1$) to infinity ($u = 0$) is (c.f. Fig. 3.1): A–D–F(here is the Alfvénic critical point)–C–A–B(here is the outer critical point)–A–D. For the technical explanation of this plot check Fig. 5.1.

Figure 5.8: shows our wind model 13c. This solution has no outer critical point. Therefore the sequence of the solution logic from the stellar surface ($u = 1$) to infinity ($u = 0$) is (c.f. Fig. 3.1): A–B(here is the inner critical point)–A–D–F(here is the Alfvénic critical point)–C–A.

star. Our modification to assume that the wind is already slightly supersonic at the base of the wind is arbitrary. Somehow the wind has to become supersonic. This problem could be solved by using a different theory for the wind close to the stellar surface. Such a theory could e.g. incorporate the consequences of an optically thick wind. Further out we should smoothly switch to our wind model taking advantage of the high wind efficiency and the low angular momentum loss of our wind solutions without an inner critical point. Therefore such an alternative model must include a consistent transition from the inner to the outer regions of the wind.

We did not make yet use of the capability of our theory to describe winds which are compressed or diluted in the equatorial plane. We will discuss this aspect in a more generalized framework in Chap. 7.

Figure 5.9: shows our wind models 13 the mass loss rate $\dot{M}$ vs. the terminal velocity v_{∞} .

Chapter 6

Waves and shocks in stellar winds

This chapter is based on an article [67] by the author and his academic supervisor Prof. P. L. Biermann.

6.1 Introduction

In the previous chapters we asked for a stationary solution of the wind problem. This assumption leads to a strong simplification of the model. Such a simplified model is a good starting point for understanding a physical system by describing its time averaged features. Therefore the first models which were applied to the solar wind were stationary (c.f. Chaps. 2&4), as well. But from observations we know today that the solar wind is far from being stationary. The strong fluctuations in the solar corona heat the corona to the high temperatures, which are necessary to drive the solar wind by thermal pressure. Therefore even the time averaged features of the solar wind can not be understood without taking fluctuations into account. Therefore it is quite possible that the wind of hot stars can not be described properly without taking fluctuations into account.

The analysis of wind fluctuations breaks into three parts: (1) How are fluctuations generated? And how do they develop in the stellar wind? (2) Which consequences do they have for the overall model of the wind? And (3) which influence does fluctuations have on observations?

Wind fluctuations can have two consequences for observation: (1) Is it possible to observe fluctuations directly by analyzing the time dependence of observational parameters like line profiles? (2) How do fluctuations influence the derivation of physical parameters like mass loss rate and terminal velocity from observational parameters like spectra and fluxes? Since this thesis is a theoretical orientated work, we do not want to go too deep into observational details here. Observed fluctuations can have two reasons: (1) Periodic fluctuations are probably connected to the stellar rotation. Some localized feature on the rotating stellar surface perturbs the wind in the line of sight periodically. This scenario is similar to a pulsar. Such fluctuations have e.g. been observed by Gagné et al. [21]. These observations allow to measure the stellar rotation rate, which is crucial for our models. Gagné et al. call θ^1 Orionis an ‘oblique magnetic rotator’ with a rotation period of 15.422 days. This star therefore rotates with 3% of its critical rotation rate. (2) The second type of fluctuations have a stochastic characteristic. This type of fluctuations are presumably created in the wind by some kind of plasma instability. We will discuss such instabilities in this chapter. Further evidence for fluctuations are the observed X-ray and nonthermal radio emission. Lucy [36] proposed that the observed X-rays are emitted by very hot plasma, which is heated up by shocks. Shocks are required as well to explain the nonthermal radio emission observed by Bieging et al. [5] from OB stars and by Abbott et al. [4] from Wolf-Rayet stars. This nonthermal radio emission is in fact synchrotron emission by relativistic electrons. Therefore this gives clear evidence for non-negligible magnetic fields on these stars. The relativistic electrons can be produced by Fermi acceleration in shocks. In binary systems these shocks could be created by the colliding winds of the two components. For single stars intrinsic wind instabilities are the only possible source for the required shocks.

Fluctuations in the wind influence the observation of basic wind parameters like the terminal velocity and the mass loss rate. The *observed* terminal velocity v_∞ is inferred from the blue edge of P-Cygni lines. This is in fact the maximal velocity reached by a significant fraction of the wind material. In the case of an permanently accelerating stationary wind this is approximately the theoretical terminal velocity $v_\infty = v(r = \infty)$. But if we have fluctuations in the wind where regions of temporarily enhanced wind velocity have simultaneously an enhanced density, we will see the enhanced velocity as the blue edge of the P-Cygni lines. In the linear theory such simultaneously enhancements are described by outward running waves. This enhanced velocity is in the case of linear waves the unperturbed v_∞ plus the velocity amplitude of the waves or, if *outward* running waves have already steepened into outward running shocks, the unperturbed v_∞ roughly plus the speed of the shock front. The latter scenario was used by Lucy to explain the X-ray emission from these stars.

The observed values for the mass loss rate $\dot{M}$ are influenced by waves in two ways: (i) $\dot{M}$ is inferred from observed values of the density ρ by $\dot{M} \sim \rho r^2 v_\infty$. An overestimated v_∞ therefore leads to an overestimated $\dot{M}$. (ii) The values for ρ are inferred from observed radio or UV fluxes. A matter distribution perturbed by waves or shocks generates higher fluxes, which lead to higher values for ρ if the perturbations are not taken into account properly (Abbott et al. [3] and Hillier [24]). The nonthermal contribution to the radio emission additionally increases the estimates for ρ , if it is not properly separated from the thermal emission. Fluctuations can also be an additional source and transport mechanism for momentum. When waves are amplified by radiation they extract extra momentum from the radiation and therefore increase the overall efficiency of radiation pressure. When these linear waves later dissipate or steepen into shocks, they transfer their momentum to the wind. This effect was analyzed by Koninx [30]. Koninx model and our discussion about the derivation of observed values for $\dot{M}$ and v_∞ are valid only if the wind is dominated by *outward* running waves.

The fluctuations in the solar wind are generated in the convective envelope of the sun. From there they propagate into the wind. At the base of the wind they heat up the plasma to the very high temperatures ($\sim 10^6\text{K}$) of the corona. Hot stars do not have a convective envelope. Their envelope is mostly radiative. Such a radiative envelope will not produce strong fluctuations and therefore presumably no corona. Therefore we need another mechanism to produce fluctuations. A good candidate is the radiative line driving force. This force is the dominating driving mechanism for the unperturbed wind. Any instability in this force could create significant fluctuations. The possibility for such an instability was already mentioned by Castor, Abbott and Klein in their famous paper about line driven winds [16].

This idea was later elaborated by several authors. MacGregor et al. [41] developed a model for short, optical thin waves. They found that these waves are unstable and grow rapidly. This result was opposed by Abbott [1], who found stable waves assuming long wavelengths. Owocki and Rybicki [52] unified these contradicting models by a more elaborate, but still analytical linear model for all wavelengths. This model showed that waves with short wavelength ($\lambda \lesssim L_S$) will grow rapidly. They refined their model later in a series of papers [53, 54, 63, 55]. The basic results is that in the thin part of the wind fluctuations are strongly amplified. The fluctuations are dominated by inward running waves steepening into shells of increased velocity but decreased density. These fluctuations are advected outward by the average wind. These papers all do a linear analysis of the fluctuations. Krolik & Raymond [31] and MacFarlane & Cassinelli [40] analyzed the structure of a single outward running shock shell in a nonmagnetic wind and found that the shock shell is driven by the radiation field to a velocity much higher than the velocity of sound and therefore much higher than the phase velocity for outward running linear waves found by Owocki & Rybicki [52]. But later Owocki et al. [56] found in a nonlinear time dependent calculation, that waves in the stellar wind are dominantly running inward and steepen into inward running, reverse shocks. This confirmed their previous result from linear analysis.

The aim of this chapter is to show in the limit of a linear analysis that the objections of Owocki et al. [56] do not apply, if a strong magnetic field and rotation are present. Therefore we connect the ideas of a rotating magnetic field, developed in the previous chapters, and of unstable waves (Owocki & Rybicki [52] in the wind of a massive star and do a linear stability analysis. We show that the magnetic field increases the number of wave modes and changes their properties significantly. High phase velocities can be achieved due to the high Alfvén velocity. Therefore inward running waves will not be advected outward and will not steepen into reverse shocks anymore, which dominate at large radii. Furthermore outward and inward running waves have the same growth timescale in the short wavelength regime where both modes are unstable. So we can expect outward running waves far from the star and forward shocks in the nonlinear regime.

In Sect. 6.2 we outline the model of Owocki & Rybicki [52] for the radiative instability. In Sect. 6.3 we derive the dispersion relation for radiatively amplified waves in the presence of a magnetic field. In Sect. 6.4 we discuss our unperturbed wind models. In Sect. 6.5 we discuss the waves we found for the wind models of Sect. 6.3. In Sect. 6.6 we discuss the observational consequences of our model. And in Sect. 6.7 we describe some conclusions.

6.2 The radiative Instability model of Owocki & Rybicki

In this section we outline briefly the model for the radiative instability of Owocki & Rybicki [52], which we are going to use for our linear analysis of radiative instabilities in magnetic winds. A more detailed treatment including several refinements can be found in the original paper and in the subsequent series of papers [53, 54, 63, 55]. We start our analysis with the radiative acceleration by a single line as described by Eq. 3.19 in Sect. 3.3. If we assume that the average wind is perturbed by a small, linear fluctuation, we can describe the perturbed line force¹ $g_L = \bar{g}_L + \delta g_L$ to first order in the perturbed optical depth $\tau = \bar{\tau} + \delta\tau$ and the line profile $\phi(\hat{x}) = \bar{\phi}(\hat{x}) - \phi'(\hat{x})\delta v_r(r)/v_{th}$ perturbed by the Doppler shift due to the velocity fluctuation. But we assume

¹Variables marked with a $\bar{}$ refer in this chapter to the unperturbed wind.

that the temperature remains constant.

$$\delta g_L(r, \kappa_L) = -g_{\text{thin}} \int_{-\infty}^{\infty} \left(\phi(\hat{x}) \delta \tau(\hat{x}, r) + \phi'(\hat{x}) \frac{\delta v_r(r)}{v_{\text{th}}} \right) e^{-\tau(\hat{x}, r)} d\hat{x} \quad (6.1)$$

Now we can integrate by parts the second term of the integrand using the Sobolev approximation for the quantities of the *unperturbed* wind.

$$\delta g_L(r, \kappa_L) \approx -g_{\text{thin}} \int_{-\infty}^{\infty} \phi(\hat{x}) \left(\delta \tau(\hat{x}, r) - \frac{\delta v_r'(r)}{v_r'(r)} \right) e^{-\tau(\hat{x}, r)} d\hat{x} \quad (6.2)$$

We assumed that the line opacity κ_L is not affected by the perturbation. From Eq. 3.20 we can derive the perturbation of the optical depth

$$\delta \tau(\hat{x}, r) = \int_R^r \left(\kappa_L \delta \rho(\tilde{r}) \phi(\tilde{x}) - \rho(\tilde{r}) \phi'(\tilde{x}) \frac{\delta v_r(r)}{v_{\text{th}}} \right) d\tilde{r} \quad (6.3)$$

$$\approx \int_R^r \kappa_L \rho \left(\frac{\delta \rho}{\rho} - \frac{\delta v_r'(\tilde{r})}{\bar{v}_r'(\tilde{r})} \right) \phi(\tilde{x}) d\tilde{r}. \quad (6.4)$$

$$\approx \bar{\tau}_L \int_{\hat{x}}^{\infty} \frac{\delta \tau_L}{\bar{\tau}_L} \phi(\tilde{x}) d\tilde{x} \quad (6.5)$$

Here we used the same trick as for δg_L to get rid of the ϕ' term. In the WKB approximation, that gradients of the mean flow are small, we can use

$$\frac{\delta \tau_L}{\bar{\tau}_L} = \frac{\delta \rho}{\bar{\rho}} - \frac{\delta v_r'(\tilde{r})}{\bar{v}_r'(\tilde{r})} \approx -\frac{\delta v_r'(\tilde{r})}{\bar{v}_r'(\tilde{r})}. \quad (6.6)$$

In our linear analysis we can describe the perturbation by a sinusoidal wave $\delta v_r(r) \approx \delta v_r e^{ikr}$. In the limit of a strong line ($\tau_L \gg 1$) we can find a simple expression for δg_L .

$$\frac{\delta g_L}{\delta v_r} = \frac{ik L_S g_{\text{thin}} \bar{\tau}_L}{v_{\text{th}}} \int_{-\infty}^{\infty} \phi(\hat{x}) e^{-\tau(\hat{x}, r)} \int_{\hat{x}}^{\infty} \phi(\tilde{x}) e^{ik\tilde{r}} d\tilde{x} d\hat{x}. \quad (6.7)$$

As in Chap. 3 we can assume that $\tilde{x}$ is close to $\hat{x}$ and therefore use

$$\tilde{x} \approx \hat{x} - \frac{v_r'(r)}{v_{\text{th}}} (\tilde{r} - r). \quad (6.8)$$

This leads to

$$\frac{\delta g_L}{\delta v_r(r)} = \frac{ik L_S g_{\text{thin}} \bar{\tau}_L}{v_{\text{th}}} \int_{-\infty}^{\infty} \phi(\hat{x}) e^{-\tau(\hat{x}, r)} \int_{\hat{x}}^{\infty} \phi(\tilde{x}) e^{-ik L_S (\tilde{x} - \hat{x})} d\tilde{x} d\hat{x}. \quad (6.9)$$

For a strong line ($\bar{\tau}_L \gg 1$) Eq. 6.9 can be approximated analytically. We shift the integration from frequencies (x) to optical depths (τ) using

$$\frac{\partial \tau(x, r)}{\partial x} = -\bar{\tau}_L \phi(x). \quad (6.10)$$

The $\exp \tau(\hat{x}, r)$ term restricts any significant contribution to the integral to the frequency range where $\hat{\tau} = \bar{\tau}(\hat{x}, r)$ is close to one. So we define x_b by

$$\bar{\tau}(x_b, r) \equiv 1. \quad (6.11)$$

We can now express $\hat{x}$ and $\tilde{x}$ to first order by

$$\tilde{x} - \hat{x} = -\frac{\tilde{\tau} - \hat{\tau}}{\bar{\tau}_L \phi(x_b)}. \quad (6.12)$$

This leads to

$$\frac{\delta g_L}{\delta v_r(r)} = \frac{ik L_S g_{\text{thin}}}{v_{\text{th}} \bar{\tau}_L} \int_{\bar{\tau}_L}^0 e^{-\hat{\tau}} \int_{\hat{\tau}}^0 \exp \left(ik L_S \frac{\tilde{\tau} - \hat{\tau}}{\phi(x_b) \bar{\tau}_L} \right) d\tilde{\tau} d\hat{\tau} \quad (6.13)$$

$$= \frac{g_{\text{thin}} \phi(x_b)}{v_{\text{th}}} \int_{\bar{\tau}_L}^0 \exp \left(- \left(\frac{ik L_S}{\phi(x_b) \bar{\tau}_L} + 1 \right) \hat{\tau} \right) - e^{-\hat{\tau}} d\hat{\tau} \quad (6.14)$$

$$\approx \omega_b \frac{ik}{\chi_b + ik}, \quad (6.15)$$

where we used the convention of Owocki & Rybicki [52]

$$\omega_b = \frac{g_{\text{thin}}\phi(x_b)}{v_{\text{th}}} \quad (6.16)$$

$$\chi_b = \rho\kappa_L\phi(x_b). \quad (6.17)$$

The radiative acceleration of a hot star wind is not properly described by the acceleration due to a single line. Therefore we can not expect that Eq. 6.15 properly describes the perturbation in the radiative acceleration. It is rather necessary to sum δg_L for an ensemble of lines using the same recipe as CAK used for the unperturbed wind. The CAK model takes the large number of weak lines into account, as well. Therefore we can not use Eq. 6.15, when we integrate over the line distribution function. But for a Doppler line profile

$$\phi_D(x) = \frac{1}{\sqrt{\pi}}e^{-x^2} \quad (6.18)$$

Eq. 6.9 can be integrated to

$$\frac{\delta g_L}{\delta v_r(r)} = \frac{ikL_S g_{\text{thin}} \bar{\tau}_L}{2v_{\text{th}}\sqrt{\pi}} \int_{-\infty}^{\infty} e^{-2\hat{x}^2} e^{-\tau(\hat{x},r)} W\left(i\hat{x} - \frac{kL_S}{2}\right) d\hat{x} \quad (6.19)$$

$$W(ix) = \exp(x^2)\text{erfc}(x), \quad (6.20)$$

where

$$\text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^{\infty} e^{-y^2} dy \quad (6.21)$$

is the complementary error function. We find then for the perturbed line acceleration analogous to Eq. 3.33

$$\frac{\delta g_{\text{cak}}}{\delta v_r(r)} = \int_0^{\infty} N(\nu_L, \kappa_L) \frac{\delta g_L(r, \nu_L, \kappa_L)}{\delta v_r(r)} d\kappa_L \quad (6.22)$$

$$\approx \frac{ikL_SF}{2\sqrt{\pi}c^2} \kappa_0^{1-\alpha_{\text{cak}}} \left(\frac{v'_r}{\rho v_{\text{th}}}\right)^{\alpha_{\text{cak}}} \Gamma(\alpha_{\text{cak}} + 1) \times \int_{-\infty}^{\infty} \left(\int_{\hat{x}}^{\infty} e^{-x^2} dx\right)^{-\alpha_{\text{cak}}-1} W\left(i\hat{x} - \frac{kL_S}{2}\right) e^{-2\hat{x}^2} d\hat{x} \quad (6.23)$$

$$\approx 2^{\alpha_{\text{cak}}} \alpha_{\text{cak}} (1 - \alpha_{\text{cak}}) \frac{g_{\text{cak}}}{v_{\text{th}}} \frac{ikL_S}{\sqrt{\pi}} \times \int_{-\infty}^{\infty} e^{(\alpha_{\text{cak}}-1)\hat{x}^2} \frac{W\left(i\hat{x} - \frac{kL_S}{2}\right)}{W(i\hat{x})^{\alpha_{\text{cak}}+1}} d\hat{x}. \quad (6.24)$$

Owocki & Rybicki [52] analyzed this integral numerically. From this analysis they found that Eq. 6.24 can nicely be approximated by the analytical expression

$$\frac{\delta g_{\text{cak}}}{\delta v_r(r)} = \Omega_{\text{OR}} \frac{ik}{\chi_{\text{OR}} + ik}, \quad (6.25)$$

which is just a modified version of the analytical expression for a single strong line (Eq. 6.15). The combined amplification rate of all lines is given by

$$\Omega_{\text{OR}} = \sqrt{\frac{2c^{\alpha_{\text{cak}}-1/2}}{1 - \alpha_{\text{cak}}}} \frac{\bar{v}_r}{L_S}. \quad (6.26)$$

And

$$\chi_{\text{OR}} = \sqrt{\frac{2c^{\alpha_{\text{cak}}-1/2}}{1 - \alpha_{\text{cak}}}} \frac{1}{L_S} = \frac{\Omega}{\bar{v}_r} \quad (6.27)$$

is the mean blue-edge absorption strength. Here c is not the speed of light but an empirical parameter: $c \approx 1.6$.

Owocki & Rybicki [52] were criticized by Lucy [37] for the neglect of damping due to diffuse radiation. But Owocki & Rybicki [53] showed that this effect reduces the amplification rate only by approximately 50% at one stellar radius and 20% at infinity. In this initial analysis we emphasize the effect of the magnetic field. Therefore we choose the simple description of Owocki & Rybicki [52] instead of the more exact but also more involved description of Owocki & Rybicki [53] or the description of Gayley & Owocki [22], who analyzed the instability in optically thick winds.

6.3 The dispersion relation

To analyze waves in the wind of hot stars we start from the equations of magnetohydrodynamics for a compressible, nonviscous, perfectly conducting fluid as described in Jackson [27] and add the analytic description of Owocki & Rybicki [52] for the influence of the stellar radiation on the plasma. We start with the time dependent equations for a nonviscous, perfectly conducting gas:

$$0 = \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \quad (6.28)$$

$$0 = \rho \frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v} \cdot \nabla) \mathbf{v} + \nabla p + \frac{\mathbf{B}}{4\pi} \times (\nabla \times \mathbf{B}) - \mathbf{F}_{\text{rad}} \quad (6.29)$$

$$0 = \frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{v} \times \mathbf{B}) \quad (6.30)$$

where $\mathbf{F}_{\text{rad}}$ is the force term due to radiation pressure. Now we express the pressure p by $v_s^2 \rho$, where v_s is the speed of sound, and replace ρ , $\mathbf{v}$, and $\mathbf{B}$ by sums of a equilibrium value and a perturbation. In the comoving reference frame ($\bar{\mathbf{v}} = 0$) this is:

$$\rho = \bar{\rho} + \delta\rho(\mathbf{x}, t) \quad (6.31)$$

$$\mathbf{v} = \delta\mathbf{v}(\mathbf{x}, t) \quad (6.32)$$

$$\mathbf{B} = \bar{\mathbf{B}} + \delta\mathbf{B}(\mathbf{x}, t) \quad (6.33)$$

Equations 6.28–6.30 give to first order in small quantities:

$$0 = \frac{\partial \delta\rho(\mathbf{x}, t)}{\partial t} + \bar{\rho} \nabla \cdot \delta\mathbf{v}(\mathbf{x}, t) \quad (6.34)$$

$$0 = \bar{\rho} \frac{\partial \delta\mathbf{v}(\mathbf{x}, t)}{\partial t} + v_s^2 \nabla \delta\rho(\mathbf{x}, t) + \frac{\bar{\mathbf{B}}}{4\pi} \times (\nabla \times \delta\mathbf{B}(\mathbf{x}, t)) - \delta\mathbf{F}_{\text{rad}} \quad (6.35)$$

$$0 = \frac{\partial \delta\mathbf{B}(\mathbf{x}, t)}{\partial t} - \nabla \times (\delta\mathbf{v}(\mathbf{x}, t) \times \bar{\mathbf{B}}) \quad (6.36)$$

We assume now, that the radiative force acts only in radial direction and depends only on the radial velocity. These equations can be reduced to a single equation for $\delta\mathbf{v}$:

$$0 = \frac{\partial^2 \delta\mathbf{v}(\mathbf{x}, t)}{\partial t^2} - v_s^2 \nabla (\nabla \cdot \delta\mathbf{v}(\mathbf{x}, t)) + \bar{\mathbf{v}}_A \times \nabla \times [\nabla \times (\delta\mathbf{v}(\mathbf{x}, t) \times \bar{\mathbf{v}}_A)] - \frac{1}{\bar{\rho}} \frac{\partial \delta v_r(\mathbf{x}, t)}{\partial t} \frac{\partial f_{\text{rad}}}{\partial v_r} \mathbf{e}_r \quad (6.37)$$

with the vectorial Alfvén velocity $\bar{\mathbf{v}}_A = \bar{\mathbf{B}}/\sqrt{4\pi\bar{\rho}}$. If we use the result of Owocki & Rybicki [52] for the linear perturbation of the radiative force, we can get a dispersion relation from this wave equation for plane waves:

$$\delta\mathbf{v}(\mathbf{x}, t) = \delta\mathbf{v} e^{i\mathbf{k} \cdot \mathbf{x} - i\omega t}. \quad (6.38)$$

Equation 6.37 then becomes:

$$0 = -\omega^2 \delta\mathbf{v} + (v_s^2 + v_A^2)(\mathbf{k} \cdot \delta\mathbf{v})\mathbf{k} + (\bar{\mathbf{v}}_A \cdot \mathbf{k})[(\bar{\mathbf{v}}_A \cdot \mathbf{k})\delta\mathbf{v} - (\bar{\mathbf{v}}_A \cdot \delta\mathbf{v})\mathbf{k} - (\mathbf{k} \cdot \delta\mathbf{v})\bar{\mathbf{v}}_A] - \frac{\Omega_{\text{OR}} k_r}{\chi_{\text{OR}} + i k_r} \omega (\delta\mathbf{v} \cdot \mathbf{e}_r) \mathbf{e}_r \quad (6.39)$$

Equation 6.39 is a vector equation, which is linear in $\delta\mathbf{v}$. We can think of it as a generalized eigenvalue problem:

$$(\mathbf{A}(\mathbf{k}, \bar{\mathbf{v}}_A, v_s^2) - \omega \mathbf{B}(k_r, \Omega_{\text{OR}}, \chi_{\text{OR}}) - \omega^2 \mathbb{I}) \delta\mathbf{v} = 0, \quad (6.40)$$

where $\mathbf{A}$ and $\mathbf{B}$ are tensors. We can find ω and $\delta\mathbf{v}$ numerically. Then $\delta\mathbf{B}$ and $\delta\rho$ follow from Eqs. 6.34 & 6.36:

$$\delta\rho = \frac{\bar{\rho}}{\omega} (\mathbf{k} \cdot \delta\mathbf{v}) \quad (6.41)$$

$$\delta\mathbf{B} = \frac{1}{\omega} [(\mathbf{k} \cdot \delta\mathbf{v})\bar{\mathbf{B}} - (\bar{\mathbf{B}} \cdot \mathbf{k})\delta\mathbf{v}] \quad (6.42)$$

Although Eq. 6.40 is very involved in the general case, we can find an analytical solution for a simplified situation:

$$\mathbf{k}(r) = k\mathbf{e}_r \quad (6.43)$$

$$\bar{\mathbf{v}}_A(r) = \bar{v}_A\mathbf{e}_\phi \quad (6.44)$$

The latter approximation is quite accurate far away from the star. In this limit we find

$$\omega = -\frac{\Omega_{\text{OR}}k}{2(\chi_{\text{OR}} + ik)} \pm \sqrt{\left(\frac{\Omega_{\text{OR}}k}{2(\chi_{\text{OR}} + ik)}\right)^2 + (v_s^2 + \bar{v}_A^2)k^2}. \quad (6.45)$$

In the long wavelength limit ($k \ll \chi_{\text{OR}}$), where the waves are stable, this leads to

$$\omega = \left[-\frac{\bar{v}_r}{2} \pm \sqrt{\frac{\bar{v}_r^2}{2} + v_s^2 + \bar{v}_A^2} \right] k. \quad (6.46)$$

In the case of a weak magnetic field with $\bar{v}_r \gg v_s \gtrsim \bar{v}_A$, this resembles Abbott's [1] result for stable radiative-acoustic waves with a fast inward and a slow outward mode. In the case of a strong magnetic field we have $\bar{v}_r \approx \bar{v}_A \gg v_s$. This leads to higher phase velocities for both modes and reduces the relative difference between inward and outward waves. Additionally inward running waves are not advected outward by the average wind motion any more, because their phase velocity is higher than the velocity of the unperturbed wind. In the short wavelength limit ($k \gg \chi_{\text{OR}}$) we find

$$\omega = i\frac{\Omega_{\text{OR}}}{2} \pm \sqrt{-\frac{\Omega_{\text{OR}}^2}{4} + (v_s^2 + \bar{v}_A^2)k^2}. \quad (6.47)$$

These waves propagate, if Ω_{OR} is less than $2k\sqrt{v_s^2 + \bar{v}_A^2}$, with the same phase velocity inward and outward. The amplification rate is also the same for both modes.

In the case of no magnetic field Eq. 6.40 leads to

$$0 = \omega^3 + \frac{\Omega_{\text{OR}}k_r}{\chi_{\text{OR}} + ik_r}\omega^2 - v_s^2\mathbf{k}^2\omega - \frac{\Omega_{\text{OR}}k_r}{\chi_{\text{OR}} + ik_r}v_s^2(k_\phi^2 + k_\theta^2). \quad (6.48)$$

For $k_\theta = k_\phi = 0$ this reproduces the result for isothermal waves found by Owocicki & Rybicki [52]. For oblique waves there is a third wave mode.

6.4 The unperturbed wind models

To analyze the effect of these waves we construct three wind models for a standard massive star. Our model has $M = 23M_\odot$, $L = 1.7 \times 10^5 L_\odot$, $R = 8.5R_\odot$, $T = 60000\text{K}$, $\alpha_{\text{cak}} = 0.56$, and $k_{\text{cak}} = 0.28$. The first model (model A) is the standard analytic CAK wind for a star without magnetic field, rotation, or pressure. In this model we reproduce the previous result of dominantly inward running waves found by Owocicki et al. [56]. In the second model (model B) we add a radial magnetic field. Since this magnetic field is parallel to the natural stream lines of the wind of a nonrotating star, this field does not change the velocity profile of the unperturbed wind. But it changes the microphysics for waves. The last model (model C) is a luminous fast magnetic rotator model. The rotating magnetic field provides an additional driving force, which changes the properties of the wind drastically. The terminal velocity decreases and the mass loss rate increases. The wind efficiency $(\dot{M}v_\infty)/(L/c)$ is 3.8, which is much higher than for a purely radiatively driven wind in the single scattering limit, where the efficiency can not be higher than unity. In spite of the known spin-down problem we choose a strong magnetic field and a high rotation rate in order to emphasize the influence of these parameters. For this model we use the model from Chap. 5 (Eq. 5.1–5.4). Table 6.1 gives the magnetic field, rotation rate, and the resulting values for the above mentioned unperturbed wind models. In Sect. 6.6 we will discuss how these values and their observation can be influenced by waves. In this work we do not discuss the influence of the waves back on the unperturbed wind as Koninx [30] did. A model with rotation but without magnetic field is not included, because this model has the same microphysics for waves as model A. Just $\dot{M}$ and the velocity dependence on r are different. Model C differs from model B in the local conditions by the fact that, due to the rotational twist, the magnetic field and the direction of the radiative force are not parallel anymore. Even at the base of the wind B_ϕ is approximately $-1.67B_r$.

Table 6.1: Results for the unperturbed wind models

Model	A	B	C
B_{r0} [G]	0	500	500
$\Omega/\Omega_{\text{crit}}$	0	0	0.92
v_∞ [km s $^{-1}$]	1146	1146	784
$\dot{M}$ [$10^{-6}M_\odot$ yr $^{-1}$]	0.6	0.6	17
$R_{\tau=2/3}$ [$R_\odot$]	8.5	8.5	11
$(\dot{M}v_\infty)/(L/c)$	0.2	0.2	3.8

6.5 Numerical results for waves

Since our unperturbed wind model is limited to the equatorial plane we limit our discussion for waves to the same plane. We have still two free parameters then: The wavelength and the azimuthal angle of $\mathbf{k}$. First we will discuss radial waves. This will show all important properties of this wave model. At the end of this section we will briefly discuss the influence of the azimuth angle of $\mathbf{k}$. Figures 6.1&6.2 show numerical results for wind model A&B. The sonic wave modes² found for model A are identical to the slow magnetosonic modes of model B. For model B we find additionally four fast wave modes. These modes, the fast magnetosonic and the Alfvénic modes, have the same phase velocity $v_{\text{Ph}} \approx \bar{v}_A$, because both, $\mathbf{B}$ and $\mathbf{k}$, are parallel to $\mathbf{e}_r$. But these wave modes are stable and show no dependence on wavelength. Therefore we concentrate our discussion for model A&B on the slow waves: Fig. 6.1 shows the dependence of the waves on the wavelength for $r = 2R$, plotted relative to the Sobolev length, which is the relevant length scale for radiative wave amplification in the model of Owocki & Rybicki [52], we use here. $R = 8.5R_\odot$ is the stellar radius. In the long wavelength limit we find stable waves with a high phase velocity inward and a low phase velocity outward. This reproduces Abbott’s [1] result of radiative-acoustic waves. In the short wavelength limit we find the same amplification timescales and phase velocities (except the direction) for both modes. In this limit we would expect to see both wave modes in the wind. But the most interesting case is the bridging case $\lambda \approx L_S$. Here we find the shortest amplification timescale for all wavelengths. Inward waves are two orders of magnitude faster in amplification than outward waves. They have also a higher phase velocity. This resembles the result of Owocki et al. [56], who did a nonlinear calculation and found that primarily the inward running waves steepen into reverse shocks, which are advected outward. The aim of this chapter is to argue that this scenario changes if a magnetic field *and* rotation are involved. Figure 6.2 shows the radial dependence of the wave with $\lambda = L_S(r) = v_{\text{th}}/v'_r$. The phase velocity for the slow magnetosonic modes is approximately the velocity of sound, so that inward running waves are advected outward in the supersonic part of the wind. The amplification of the waves is strongest close to the star, where the Sobolev length is short. The phase velocity of the fast modes goes with r^{-1} for large radii since $B = B_r \sim r^{-2}$. This might lead to a small velocity for outward running shocks at large radii.

Figures 6.3&6.4 show the same plots for model C – with magnetic field and rotation. The crucial point is that the magnetic field and the amplifying stellar radiation are not parallel anymore. For large radii they are even perpendicular. Therefore the fast magnetosonic wave modes, which are most interesting for us, are amplified as well. Figure 6.3.b shows six modes with different phase velocities. Two of them, the Alfvénic modes, show no dependence on wavelength. They are unaffected by the radiation field and therefore stable. Figure 6.3.a shows the amplification timescales for the magnetosonic waves. The fast magnetosonic waves grow approximately one order of magnitude faster than the slow waves. We can therefore expect that these waves will dominate. The crucial point is that they are much faster than the unperturbed wind – especially close to the star. Inward running fast waves will therefore not be advected away from the star. Figure 6.4.b shows that the phase velocity for the fast magnetosonic waves remain high for large radii. This velocity is a lower limit for the velocity of outward running shocks. Rybicki et al. [63] showed that non-radial perturbations in the stellar wind are damped close to the wind. But the magnetic field of our model C is mostly tangential already at the stellar surface. For the fast magnetosonic modes $|\delta v_\phi/\delta v_r|$ is 0.5 at the stellar surface and 0.35 at $r = 2R$. We expect therefore, that the effects found by Rybicki et al. will influence but not completely dampen the magnetosonic waves. We emphasize that fast magnetosonic waves propagate fastest perpendicular to the magnetic field with $v_{\text{Ph}} = (\bar{v}_A^2 + v_s^2)^{0.5}$.

It is very speculative to draw conclusions for nonlinear waves and shocks from a linear stability analysis.

²Ordered by the radial phase velocity we denote in our figures the fast magnetosonic modes with 1&6, the Alfvénic modes with 2&5, and the slow magnetosonic modes with 3&4. The sonic modes of model A, which are identical to the slow magnetosonic modes of model B, are denoted with 3&4 as well.

Figure 6.1: Amplification timescales (a) and phase velocities (in the frame of the unperturbed wind) (b) versus wavelength for model A&B and $r = 2R$. In model A only modes 3&4 exist. Modes missing in Fig. a) are stable. Mode 3 with $\lambda \approx L_S$ has the shortest amplification timescale and therefore will dominate the wind. These inward running waves are advected outward with $\bar{v}_r = 811 \text{ km s}^{-1}$ and steepen into reverse shocks.

Figure 6.2: Amplification timescales (a) and phase velocities (in the frame of the unperturbed wind) (b) versus radius for model A&B and $\lambda = L_S$. In model A only modes 3&4 exist. Modes missing in Fig. a) are stable. The wave amplification is strongest close to the star, where the radiation field and wind acceleration are strong. Inward running waves originating there will be advected outward and steepen into reverse shocks.

Figure 6.3: Amplification timescales (a) and phase velocities (in the frame of the unperturbed wind) (b) versus wavelength for model C and $r = 2R$. Modes missing in Fig. a) are stable. In the long wavelength limit all modes are stable. In the short wavelength limit the fast magnetosonic modes (1&6) grow approximately one order of magnitude faster as the slow magnetosonic modes (3&4). We expect that fast magnetosonic waves in both directions are equally dominant in the wind of model C. Since the magnetosonic waves are much faster than the unperturbed wind ($\bar{v}_r = 294 \text{ km s}^{-1}$), the inward running waves will not be advected outward. The stable Alfvénic modes (2&5) show no dependence on wavelength.

Figure 6.4: Amplification timescales (a) and phase velocities (in the frame of the unperturbed wind) (b) versus radius for model C and $\lambda = 0.1L_S$. The Alfvénic modes (2&5) missing in Fig. a) are stable. The wave amplification is strongest close to the star, where radiation field and wind acceleration are strong. Fast magnetosonic waves originating here will dominate the wind. They have the shortest amplification timescale for all radii and a high phase velocity even at large radii. This may lead to fast shocks running outward, which have a strong influence on observation.

But we showed that a magnetic field has a strong influence on the linear analysis. Therefore we expect a strong influence of the magnetic field on nonlinear perturbations as well. Our speculative scenario for waves in the wind of hot stars is the following: Waves are predominantly generated close to the star where the stellar radiation field is strong and the Sobolev length is short. Waves with a wavelength short compared to the Sobolev length are generated predominantly, because they have the shortest amplification timescale. Inward running waves run into the star and disappear because their phase velocity is higher than the unperturbed wind velocity. Outward running waves, which have, for short wavelengths, the same growth timescale than inward running waves, can run over many stellar radii and grow. For the outward running waves $\delta\rho$ and δv_r are in phase. Therefore they can steepen into forward shocks with regions of high density at high velocity and influence the observation of the terminal velocity and mass loss rate.

The picture drawn in the last section does not change significantly when non-radial waves are taken into account. There are two new effects compared to the radial case. A third wave mode appears in model A as predicted by Eq. 6.48. This inward running mode has a long amplification timescale and a relatively low phase velocity. Therefore we do not expect a significant contribution of this mode to the situation in the wind of model A. For model B we find that Alfvén and fast magnetosonic waves have different phase velocities now. The fast magnetosonic waves are now amplified, too. But their amplification timescale is much longer than for slow magnetosonic waves.

6.6 Consequences of our model

In this chapter we do a linear stability analysis and show that the waves in the stellar wind can help to understand the observations. In order to calculate quantitative results, which can be compared with observations, it would be necessary to analyze the detailed properties of the shocks resulting from the waves found in this chapter. But we can derive some estimates from our calculations.

From Fig. 6.4.b we see that the phase velocity of the outward running waves and possibly shocks in the rest frame of the star is at least twice the terminal velocity of the unperturbed wind. In the outward running waves the oscillations of v_r and ρ are in phase. Therefore a significant amount of matter, but presumably not all matter will escape at this or a higher velocity, if the outward running waves steepen into forward shocks. The terminal velocity will then be overestimated at least by a factor of two in the observation. For our model C this would be $v_{\infty, \text{obs}} \approx 1500 \text{ km s}^{-1}$. Krolik & Raymond [31] found that in a nonmagnetic wind shock shells are running much faster than the phase velocity of the waves. In an unperturbed magnetic wind model such a high value for v_{∞} combined with an reasonable high value for $\dot{M}$ can only be obtained with a very high magnetic field and fast rotation, which leads to a spin-down problem.

The influence of our model on $\dot{M}$ is more difficult to estimate. We gain a real factor on 28 in $\dot{M}$ between our model A&B and model C even in the unperturbed wind due to the driving force of the rotating magnetic field. Furthermore the observation of $\dot{M}$ is influenced by the clumping of the wind matter. But to calculate the clumping factor $\langle \rho^2 \rangle / \langle \rho \rangle^2$ at large radii, where radio observations are made, it would be necessary to do a nonlinear calculation including large radii, because the waves steepen into shocks very rapidly due to the short amplification timescales. This is beyond the linear model presented here.

6.7 Conclusions

In this chapter we analyzed the interaction between a magnetic field and linear waves induced by the radiative instability. We found both models complement each other. The magnetic field suppresses the inward running waves, which dominate in nonmagnetic winds. This may allow the outward running waves to support the unperturbed wind as described by Koninx [30] and to form high density shock shells running out at a high speed. These shock shells may explain the high terminal velocities measured in winds of massive stars. The outward running waves will also lead to an overestimation of $\dot{M}$ due to wind clumping and the overestimated v_{∞} . Wind clumping also occurs without a magnetic field. But in this case the resulting shock shells will run inward; and the argument about the overestimated v_{∞} would not apply. The overestimated $\dot{M}$ and v_{∞} put unnecessarily strong restrictions on fast magnetic rotator wind models. We argued that even for a magnetic field with $B_{r0} = 500 \text{ G}$ the spin-down time is consistent with the lifetime of the star inferred from the mass loss rate considering the uncertainties in the stellar structure. From the observation of nonthermal radio emission in many OB and Wolf-Rayet stars we know that these stars have a non-negligible magnetic field. Further direct observations are necessary to infer the actual strength of these fields. Previous observations using the Zeeman effect were due to the strong Doppler broadening of the lines not sensitive enough to measure reliably the magnetic field strength in the winds of O and Wolf-Rayet stars [33]. It might be possible in the near future to measure these magnetic field strengths using the Hanle effect [25, 26].

Figure 6.5: Expansion time versus radius. Model C has a slower acceleration close to the star and a lower terminal velocity. A fast magnetosonic wave with an amplification timescale of about 2500s (cf. Fig 6.4.a) grows by a factor of $\approx e^{40}$, while the wind expands from $r = 1R$ to $r = 1.5R$. The electron scattering opacity is $^{2/3}$ at $r = 1.3R$. Therefore we can expect shocks already at this radius, where line observation starts. The objections of Lucy [37] do not change this situation qualitatively.

We showed that a luminous fast magnetic rotator model plus wind perturbations by waves or shocks can help to explain the observed high values for $\dot{M}$ and v_{∞} without being ruled out by the spin-down problem. Further observation of the magnetic field and further theoretical work on the evolution of stellar rotation are necessary to evaluate the role of magnetic fields in winds of massive hot stars.

Chapter 7

The two dimensional fluxsheet model

7.1 Introduction

In Chap. 5 we discussed an equatorial wind driven by radiation and magnetic fields. In this chapter we extend our discussion to the non-equatorial region. This is necessary to get better quantitative results for mass and angular momentum loss (cf. Sect. 4.5). It has also been argued that the observed high mass loss rates and terminal velocities are not created in the same regions of the wind [61, 62]. Furthermore it is possible to apply a non-equatorial model to winds from accretion disks. This can be important for some types of stars and for Active Galactic nuclei (AGN). It is obvious that disks rotate close to the critical (Keplerian) rotation rate. And it is widely assumed that the magnetic field is a major mechanism to extract angular momentum from the disk and to drive winds and jets [11]. But the role of radiation from the central object or from a hot disk is often underestimated.

In this chapter we derive a model for a non-equatorial wind driven by radiation and magnetic fields. Our model is again based on the fluxsheet concept and therefore essentially one dimensional. But we generalize the model of Chaps. 4&5 by dropping the restriction that the fluxsheet has to lie in the equatorial plane. In App. A we will show the equations of Chaps. 4&5 follow from the generalized equations developed here. At the end of the chapter we will show results from first numerical exploration of the model.

In the first part we follow closely the derivation of Lovelace et al. [35] to reduce the equations for a rotational symmetric, rotating, stationary, and perfectly conducting MHD flow to the fluxsheet concept. Since we are primarily analyzing winds from stars and not from disks we shifted the derivation from cylindrical to spherical coordinates. The goal of Lovelace et al. is to derive an ordinary differential equation for the flow in the fluxsheet from Bernoullis equation of energy conservation. This is reasonable for a pure MHD model. But we can not go this way because, opposite to Lovelace et al., we want to include radiation as a major wind driving mechanism. We saw in Chap. 3 that we have no simple theory for the energy exchange between radiation and matter. The Thompson and the CAK theory, both give us only a source term for momentum. Therefore we leave the path of Lovelaces model and derive a final ordinary differential equation from Eulers equation of momentum balance. This equation is a vector equation. We take only the component parallel to the a priori given fluxsheet into account. The component perpendicular to the fluxsheet can be used to improve the shape of the fluxsheet.

In Sect. 7.2 we follow to derivation of Lovelace et al. for the basic equations in the fluxsheet description. In Sect. 7.3 we introduce our fluxsheet coordinate system with its a priori given shape. In Sect. 7.4 we use the results of the two previous sections to derive our final wind equation as a single ordinary differential equation. In Sect. 7.5 we derive the transverse component of the Euler equation, which was neglected in the previous section. It allows an improvement of the chosen fluxsheet shape. and finally we will give some preliminary numerical results in Sect. 7.6 to show the capabilities of this model.

7.2 The basic model equations

As in Chap. 4 we start from the equations of ideal magneto-hydrodynamics (MHD) in a quasi stationary situation (Eq. 4.1–4.5). Again we assume that the wind is rotational symmetric and neglect therefore all dependencies on the azimuthal angle ϕ . But now we do not set v_θ and B_θ equal to zero as we did in Chap. 4. Rather we use the perfect conductivity equation

$$\mathbf{E} + \frac{1}{c} \mathbf{v} \times \mathbf{B} = 0 \quad (7.1)$$

and the axisymmetry condition $E_\phi = 0$ to find

$$\mathbf{v}_p \equiv v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta \quad (7.2)$$

$$= \kappa(r, \theta) \mathbf{B}_p, \quad (7.3)$$

where the subscript “p” denotes the poloidal component of the vector. From $0 = \nabla \cdot (\rho \mathbf{v}) = \nabla \cdot (\rho \mathbf{v}_p) = \nabla \cdot (\rho \kappa(r, \theta) \mathbf{B}_p)$, we know that

$$\mathbf{B}_p \cdot \nabla (\rho \kappa(r, \theta)) = 0, \quad (7.4)$$

because $\nabla \cdot \mathbf{B}_p$ equals $\nabla \cdot \mathbf{B} = 0$. The poloidal magnetic field can be expressed in terms of the flux function

$$\Psi = r \sin \theta A_\phi(r, \theta), \quad (7.5)$$

where A_ϕ is the azimuthal component of the vector potential. Ψ is constant on every fluxsheet, i.e.

$$\mathbf{B}_p \cdot \nabla \Psi = 0. \quad (7.6)$$

From Eq. 7.4 we get

$$4\pi \rho(r, \theta) \kappa(r, \theta) = F(\Psi), \quad (7.7)$$

where $F(\Psi)$ is a function whose only relevant feature is that F is constant along a fluxsheet. Using $|\nabla \Psi|/(r \sin \theta) = B_p$ and Eq. 7.6 we get

$$\mathbf{v} \times \mathbf{B} = \frac{1}{r \sin \theta} (v_\phi - \kappa B_\phi) \nabla \Psi. \quad (7.8)$$

From Eqs. 4.3&7.8 we know that

$$\frac{1}{r \sin \theta} (v_\phi - \kappa B_\phi) = \bar{\omega}(\Psi), \quad (7.9)$$

where $\bar{\omega}(\Psi)$ is another arbitrary function of Ψ . From Eq. 7.8 we get the electric field

$$\mathbf{E} = -\frac{1}{c} \bar{\omega}(\Psi) \nabla \Psi \quad (7.10)$$

We can now express the velocity field by

$$\mathbf{v} = \frac{F(\Psi)}{4\pi\rho} \mathbf{B}_p + \left[\frac{F(\Psi)}{4\pi\rho} B_\phi + r \sin \theta \bar{\omega}(\Psi) \right] \mathbf{e}_\phi \quad (7.11)$$

$$= \frac{F(\Psi)}{4\pi\rho} \mathbf{B} + \bar{\omega}(\Psi) \times \mathbf{r}, \quad (7.12)$$

where $\bar{\omega}$ equals $\bar{\omega}(\Psi) \mathbf{e}_z$. And $\mathbf{e}_z$ is the unit vector parallel to the rotation axis. At the base of the wind, where ρ is large, v_ϕ equals $\bar{\omega} r \sin \theta$. Therefore $\bar{\omega}$ is the angular velocity of the rotating fluxsheet. Using the toroidal component of Eq. 4.2 we find

$$\mathbf{B}_p \cdot \nabla (r \sin \theta (B_\phi - F v_\phi)) = 0, \quad (7.13)$$

which implies that

$$H(\Psi) = r \sin \theta (B_\phi - F v_\phi) \quad (7.14)$$

is another arbitrary function of Ψ . This corresponds to the conservation of angular momentum for matter moving on a given flux surface, $\Psi = \text{const}$. Now we can express v_ϕ and B_ϕ by

$$r \sin \theta B_\phi = \frac{H + r^2 \sin^2 \theta F \bar{\omega}}{1 - M_p^2} \quad (7.15)$$

$$r \sin \theta v_\phi = \frac{1}{1 - M_p^2} \left(r^2 \sin^2 \theta \bar{\omega} + \frac{F H}{4\pi\rho} \right), \quad (7.16)$$

where we have used the poloidal Alfvén Mach number

$$M_p = \sqrt{\frac{4\pi\rho \mathbf{v}_p^2}{\mathbf{B}_p^2}} \quad (7.17)$$

$$= \frac{F}{\sqrt{4\pi\rho}}. \quad (7.18)$$

On the Alfvén surface ($r = r_{\text{Ac}}, \theta = \theta_{\text{Ac}}, M_p = 1$) the denominator of Eqs. 7.15 & 7.16 vanishes. Since B_ϕ and v_ϕ must be finite on the Alfvén surface, we get the conditions

$$H = -r_{\text{Ac}}^2 \sin^2 \theta_{\text{Ac}} F \bar{\omega} \quad (7.19)$$

$$r_{\text{Ac}}^2 \sin^2 \theta_{\text{Ac}} \bar{\omega} = -\frac{FH}{4\pi\rho_{\text{Ac}}}. \quad (7.20)$$

From l'Hospital's rule we find

$$(r \sin \theta B_\phi)_A = -H \frac{d[\ln(r^2 \sin^2 \theta)]_A / ds}{d(\ln \rho)_A / ds} \quad (7.21)$$

$$(r \sin \theta v_\phi)_A = (r \sin \theta)_A^2 \bar{\omega} \left[1 + \frac{d[\ln(r^2 \sin^2 \theta)] / ds}{d(\ln \rho)_A / ds} \right] \quad (7.22)$$

$$= (r \sin \theta)_A^2 \bar{\omega} \left[1 - \frac{(r \sin \theta B_\phi)_A}{H} \right], \quad (7.23)$$

where s is the arc length along the poloidal projection of the field line, i.e. $d\Psi/ds = 0$.

7.3 The fluxsheet coordinate system

Up to this point our model is exact besides the approximation of rotational symmetry, stationarity, no viscosity, and perfect conductivity. But therefore we have still a system of two partial differential equations with two dependent (v_r, v_θ) and two independent (r, θ) variables. Such a system was solved by Sakurai for a stellar wind without radiation [64].

In order to reduce the problem from two to one dimension we split the three dimensional space into a one-parameter family of two dimensional fluxsheets. Figure 7.1 shows how these fluxsheets fit into each other like the leaves of a blossom. Every fluid element will flow along a single fluxsheet. The magnetic field lines are confined in the individual fluxsheets as well, because we assume flux freezing and a quasi stationary model. Due to the rotational symmetry of the whole wind, the fluxsheets are rotational symmetric as well. Fluxsheets exist even in a model which solves the full MHD equations. In this case we would find simultaneously the shape of the fluxsheets and the motion of the matter within the fluxsheets. We already reduced the problem from three to two spatial dimensions by assuming rotational symmetry. Now we reduce it again by one spatial dimension by using an a priori given shape for the fluxsheets and only asking for the motion within the fluxsheets. Falcke [18] integrated the equations of an radiation driven nonmagnetic wind simultaneously for the wind velocity and the shape of the fluxsheet. This is much more difficult for a magnetic wind, since our solution has to pass through three instead of one critical point. And this will only happen once we found the two eigenvalues of the equations. The wind solution has to pass through three critical point if it should extend from the subsonic base of the wind to arbitrary large radii.

We require that the shape of the fluxsheet is given by $r(u, \eta)$ and $\theta(u, \eta)$, where η is constant along the fluxsheet and u is an arbitrary parameter along the fluxsheet. Since the parameter η is constant along a fluxsheet, it depends only on the flux function Ψ introduced in Eq. 7.5 and vice versa. The reason for using η instead of the already introduced parameter Ψ is that we can choose it arbitrary in the same way as u . It just distinguishes different fluxsheets, while Ψ has a deeper physical meaning. For our purpose it is not necessary to know Ψ explicitly. Therefore it is numerically simpler to introduce η . η and u are a curved coordinate system for the meridional (r, θ) plane which is adapted to the shape of the fluxsheets. It is therefore more appropriate for solving the wind equations than the (r, θ) system. We do not give explicit formulas for $r(u, \eta)$ and $\theta(u, \eta)$ here, so that the shape of the fluxsheets remains yet unspecified. This has the advantage that the wind equations, we derive now, remain independent of the explicit shape of the fluxsheet. Later, when we start our numerical computations, we have to specify the shape of the fluxsheets through explicit formulas for $r(u, \eta)$ and $\theta(u, \eta)$. But then we can easily compute and compare models for different fluxsheet shapes by using different explicit formulas for $r(u, \eta)$ and $\theta(u, \eta)$.

Now we can define a unit vector $\mathbf{e}_p$ tangential to the fluxsheet in poloidal direction given by

$$\mathbf{e}_p(u, \eta) = \frac{s\dot{r}}{\sqrt{\dot{r}^2 + r^2\dot{\theta}^2}} \mathbf{e}_r + \frac{sr\dot{\theta}}{\sqrt{\dot{r}^2 + r^2\dot{\theta}^2}} \mathbf{e}_\theta \quad (7.24)$$

$$= e_{pr}(u, \eta) \mathbf{e}_r + e_{p\theta}(u, \eta) \mathbf{e}_\theta, \quad (7.25)$$

where the dot $\dot{}$ refers to the partial derivative with respect to u . The constant $s = |\dot{r}|/\dot{r} = \pm 1$ fixes for later convenience the orientation of $\mathbf{e}_p$ so that $\mathbf{e}_p$, per definition, always points outward. We can now express $\mathbf{v}$ and

Figure 7.1: shows the stellar surface and three members of the infinite set of fluxsheets. Every fluxsheet has a different rotation rate $\bar{\omega}(\eta)$. Whether $\bar{\omega}$ is higher at the poles or at the equator is not clear yet.

Figure 7.2: A non-equatorial fluxsheet in the (r, θ) plane. In this plane the thickness of the sheet is $dh(u)$. The rotational symmetry contributes a factor of $2\pi r \sin \theta$ to the total cross section of the fluxsheet.

$\mathbf{B}$ as functions of the fluxsheet coordinates u and η :

$$\mathbf{v} = v_p(u, \eta)\mathbf{e}_p + v_\phi(u, \eta)\mathbf{e}_\phi \quad (7.26)$$

$$\mathbf{B} = B_p(u, \eta)\mathbf{e}_p + B_\phi(u, \eta)\mathbf{e}_\phi \quad (7.27)$$

$$= \frac{4\pi\rho(u, \eta)}{F(\eta)}(\mathbf{v} - \bar{\omega}(\eta) \times \mathbf{r}) \quad (7.28)$$

In order to describe ρ and B_p in the new coordinates we need an expression for the cross section of a fluxsheet. Then we can use the conservation of matter and magnetic flux as we did in Eqs. 4.8&4.9. In Fig. 7.2 we show the wind between two infinitesimal separated fluxsheets. The cross section dA between the two fluxsheets is

$$dA = 2\pi r \sin \theta |dh|. \quad (7.29)$$

The separation between the two fluxsheets dh varies along the fluxsheets. But we can relate it to $d\eta$, which is constant along the fluxsheets:

$$d\eta = \frac{\partial \eta}{\partial h} dh(u) \quad (7.30)$$

Since η is constant along every fluxsheet and dh is measured perpendicular to the fluxsheets, we can express

$\partial\eta/\partial h$ by

$$\frac{\partial\eta}{\partial h} = |\nabla\eta(r, \theta)|. \quad (7.31)$$

Finally we find for the cross section between the fluxsheets

$$dA = 2\pi r \sin\theta \frac{|d\eta|}{|\nabla\eta|}. \quad (7.32)$$

Now we use $B_p dA = \text{const}$, $\rho v_p dA = \text{const}$, and $d\eta = \text{const}$ between the two fluxsheets to express

$$\rho = \frac{r_{Ac} \sin\theta_{Ac}}{r \sin\theta} \frac{v_{pAc}}{v_p} \frac{|\nabla\eta|}{|\nabla\eta|_{Ac}} \rho_{Ac}(\eta) \quad (7.33)$$

$$B_p = \frac{R \sin\theta_0}{r \sin\theta} \frac{|\nabla\eta|}{|\nabla\eta|_0} B_{p0}. \quad (7.34)$$

The poloidal magnetic field strength at the base of the wind B_{p0} is an input parameter of our models. The matter density at the Alfvénic critical point ρ_{Ac} will be derived from model input parameters later. Alternatively we can relate the matter density to the mass loss rate in the fluxsheet

$$\frac{\partial\dot{M}}{\partial\eta} = \rho v_p \frac{2\pi r \sin\theta}{|\nabla\eta|}. \quad (7.35)$$

If we want to calculate the real mass loss rate for our model star we must solve the wind equation for every fluxsheets from the equator to the poles and then integrate the values found for $\partial\dot{M}/\partial\eta$ over all flux sheets:

$$\dot{M}_{\text{real}} = 2 \int_{\eta(\text{pole})}^{\eta(\text{equator})} \frac{\partial\dot{M}}{\partial\eta} d\eta \quad (7.36)$$

In order to get a better intuition for the mass loss at different latitudes it is helpful to assume for a moment that the density and the wind velocity are constant at the base of the wind. Under this approximation we can integrate Eq. 7.36 neglecting the oblateness of the rotating star and find

$$\dot{M}_{\text{approx}}(\eta) = 4\pi R^2 \rho_0(\eta) v_{p0}(\eta). \quad (7.37)$$

This quantity is analogous to mass loss rate used in Chap. 5 as one of the eigenvalues we have to find numerically.

7.4 The one dimensional Euler equation

The standard way in disk wind physics is to derive v_p from Bernoulli's equation, which essentially describes the conservation of energy in the fluxsheet. We will use Euler's momentum equation (Eq. 4.2) in order to include the momentum terms for radiation pressure. Since we have already expressed v_ϕ in terms of u , η , and v_p we can neglect the ϕ component of Eq. 4.2. Theoretically it would be sufficient to integrate either the r or the θ component of Eq. 4.2. But this would lead to large numerical errors when the flow direction $\mathbf{e}_p$ has a significant component perpendicular to the chosen component of Eq. 4.2. Therefore we multiply Eq. 4.2 with $\mathbf{e}_p$ and obtain a single ordinary differential equation in v_p . This equation allows us to integrate v_p along the fluxsheet. To obtain a solution for the complete wind we have to integrate v_p along several fluxsheets.

Although we neglect for a while the force balance perpendicular to the fluxsheet, we can not neglect that v_p depends on u and η . We solve this problem by separating the variables:

$$v_p(u, \eta) = V(\eta)v(u), \quad (7.38)$$

where we use an a priori given function $V(\eta)$. This is the analogy of the *self similar* solutions of Blandford & Payne, who a priori assumed certain powerlaw dependencies of ρ and B on the cylindrical radius. Now we have a single differential equation with $v(u)$ as the only dependent variable.

But this equation still contains the differential operators ∂_r and ∂_θ . We transform these into our fluxsheet coordinates by

$$\frac{\partial}{\partial r} = u' \left(\frac{\partial}{\partial u} + \dot{v} \frac{\partial}{\partial v} \right) + \eta' \frac{\partial}{\partial \eta} \quad (7.39)$$

$$\frac{\partial}{\partial \theta} = \check{u} \left(\frac{\partial}{\partial u} + \dot{v} \frac{\partial}{\partial v} \right) + \check{\eta} \frac{\partial}{\partial \eta}, \quad (7.40)$$

where we take into account, that ρ , v_ϕ , and $\mathbf{B}$ depend on u , η , and y . For brevity we will use the following convention for partial derivatives:

$$\begin{aligned} \frac{\partial f}{\partial r} &= f' & \frac{\partial f}{\partial \theta} &= \check{f} \\ \frac{\partial f}{\partial u} &= \dot{f} & \frac{\partial f}{\partial \eta} &= \check{f} \\ \frac{\partial f}{\partial x} &= \tilde{f} & \frac{\partial f}{\partial y} &= \hat{f}. \end{aligned} \quad (7.41)$$

Here we used the already the dimensionless quantities $x = r/r_*$ and $y = v/v_*$. We can now express Eq. 4.2 multiplied by $\mathbf{e}_p$:

$$0 = \mathbf{e}_p \cdot \left[(\mathbf{v} \cdot \nabla) \mathbf{v} + \frac{\nabla p}{\rho} + \nabla \Phi - \mathbf{g}_{\text{rad}} \right] + \left(\mathbf{e}_p \times \frac{\mathbf{B}}{4\pi\rho} \right) \cdot (\nabla \times \mathbf{B}) \quad (7.42)$$

Doing all these substitutions and simplifying the result to a readable form includes a lot of complicated algebra. We used therefore the software package MATHEMATICA [71] to do most of the steps. With a small MATHEMATICA program it is possible to show that Eq. 7.42 is equivalent to

$$A_1(u, v)\dot{v} + B_1(u, v, \dot{v}) = 0 \quad (7.43)$$

with

$$A_1(u, y) = (\dot{r}u' + \dot{\theta}\check{u}) \left[vV^2 - \frac{v_s^2}{v} + \frac{4\pi\rho}{F^2}\bar{v}_\phi \left(\frac{\partial v_\phi}{\partial v} - \frac{\bar{v}_\phi}{v} \right) \right] \quad (7.44)$$

$$\begin{aligned} B_1(u, y, \dot{y}) &= (\dot{r}u' + \dot{\theta}\check{u}) \left[v_s^2 \frac{\dot{\rho}}{\rho} + \partial_u v_s^2 + \frac{4\pi\rho}{F^2}\bar{v}_\phi \left(\frac{\dot{\rho}}{\rho}\bar{v}_\phi + \dot{v}_\phi \right) \right] + \\ &(\dot{r}\eta' + \dot{\eta}\check{\theta}) \left[V\check{V}v^2 + v_s^2 \left(\frac{\dot{\rho}}{\rho} - \frac{\check{V}}{V} \right) + \partial_\eta v_s^2 + \right. \\ &\left. \frac{4\pi\rho}{F^2}\bar{v}_\phi \left(\dot{v}_\phi - \check{\omega}r \sin \theta + \bar{v}_\phi \left(\frac{\dot{\rho}}{\rho} - \frac{\check{V}}{V} - \frac{\check{F}}{F} \right) \right) \right] - \\ &\left(\frac{\dot{r}}{r} + \frac{\dot{\theta}}{\tan \theta} \right) \left[\frac{4\pi\rho}{F^2}\bar{v}_\phi (r \sin \theta \bar{\omega} - \bar{v}_\phi) + v_\phi^2 \right] + \\ &\dot{r}(\nabla \Phi - g_{\text{rad}}(u, v, \dot{v})) \end{aligned} \quad (7.45)$$

$$\bar{v}_\phi = v_\phi - r \sin \theta \bar{\omega}. \quad (7.46)$$

We can make this equation dimensionless by multiplying it with $1/(x^2 \nabla \Phi) = r_*^2/(GM)$ and introducing the length and velocity scales we used already in Chap. 4. Here we need additionally the special rules

$$vV = v_* y Y \quad (7.47)$$

$$\omega = \frac{r_*}{v_*} \bar{\omega}, \quad (7.48)$$

where $Y(\eta)$ is just a dimensionless version of $V(\eta)$. We get then

$$A_2(u, y)\dot{y} + B_2(u, y, \dot{y}) = 0 \quad (7.49)$$

$$A_2(u, y) = (\dot{x}\tilde{u} + \dot{\theta}\check{u}) \left[yY^2 - \frac{y_s^2}{y} + \frac{\bar{y}_\phi}{M_p^2} \left(\hat{y}_\phi - \frac{\bar{y}_\phi}{y} \right) \right] \quad (7.50)$$

$$\begin{aligned} B_2(u, y, \dot{y}) &= (\dot{x}\tilde{u} + \dot{\theta}\check{u}) \left[y_s^2 \frac{\dot{\rho}}{\rho} + \partial_u y_s^2 + \frac{\bar{y}_\phi}{M_p^2} \left(\frac{\dot{\rho}}{\rho}\bar{y}_\phi + \dot{y}_\phi \right) \right] + \\ &(\dot{x}\tilde{\eta} + \dot{\theta}\check{\eta}) \left[Y\check{Y}y^2 + y_s^2 \left(\frac{\dot{\rho}}{\rho} - \frac{\check{Y}}{Y} \right) + \partial_\eta y_s^2 + \right. \\ &\left. \frac{\bar{y}_\phi}{M_p^2} \left(\dot{y}_\phi - \check{\omega}x \sin \theta + \bar{y}_\phi \left(\frac{\dot{\rho}}{\rho} - \frac{\check{Y}}{Y} - \frac{\check{F}}{F} \right) \right) \right] - \\ &\left(\frac{\dot{x}}{x} + \frac{\dot{\theta}}{\tan \theta} \right) \left[\frac{\bar{y}_\phi}{M_p^2} (x \sin \theta \bar{\omega} - \bar{y}_\phi) + y_\phi^2 \right] + \\ &\dot{x} \left(\frac{1}{x^2} - a_{\text{rad}}(u, y, \dot{y}) \right). \end{aligned} \quad (7.51)$$

If we use the line-driving mechanism of Castor, Abbott, and Klein [16] plus electron scattering as description for the radiative force, a_{rad} is given by

$$a_{\text{rad}}(u, y, \dot{y}) = \frac{r_*^2}{GM} g_{\text{rad}} \quad (7.52)$$

$$= \frac{\Gamma}{x^2} + \frac{k_{\text{cak}} \Gamma}{x^2} \left(\frac{v_*}{\kappa_{\text{Th}} v_{\text{th}} \rho r_*} \right)^{\alpha_{\text{cak}}} \left| \frac{\partial y_x}{\partial x} \right|^{\alpha_{\text{cak}}} \quad (7.53)$$

$$= \frac{\Gamma}{x^2} + \frac{C(u, y)}{\dot{x}} \left| \frac{\partial y_x}{\partial x} \right|^{\alpha_{\text{cak}}} \quad (7.54)$$

$$\tilde{y}_x = \frac{\partial y_x}{\partial x} = (\dot{y} e_{\text{pr}} + y \dot{e}_{\text{pr}}) Y \tilde{u} + (\check{Y} e_{\text{pr}} + Y \check{e}_{\text{pr}}) y \tilde{\eta}. \quad (7.55)$$

The derivation of the CAK force in Chap. 3 shows that the CAK force depends on the gradient of the velocity in the direction of the driving radiation. We want to analyze the wind from a star. Therefore the photons propagate in radial direction. If this model would be applied to systems where a disk dominates the radiation field, the equation have to be modified at this point. Outside the equatorial fluxsheet the poloidal flow $\mathbf{v}_p$ and the poloidal gradient ∂_u are in general not in radial direction. This leads to the complicated relation between the two spatial derivatives of the wind velocity, $|\tilde{y}_x|$ and $\dot{y}$. Using $|\tilde{y}_x|$ instead of $\dot{y}$ is the simplest approximation for the fact that in a curved fluxsheet geometry the radiation passes through different fluxsheets. In order to compare the results from this chapter with the results from Chap. 5 we rewrite Eq. 7.49 analogous to Eq. 3.39. This allows us to use the same arguments about critical points and reduces the necessary modifications in our software. Since the CAK force term is now proportional to $|\tilde{y}_x|^{\alpha_{\text{cak}}}$ instead of $\dot{y}^{\alpha_{\text{cak}}}$ we use $|\tilde{y}_x|$ as the local unknown quantity. This leads to

$$A(u, y) |\tilde{y}_x| + B(u, y) = C(u, y) |\tilde{y}_x|^{\alpha_{\text{cak}}}. \quad (7.56)$$

Before we can use this equation we have to transfer A_2 and B_2 into A and B . Once we know $|\tilde{y}_x|$, we need a formula which gives us $\dot{y}$ as function of $|\tilde{y}_x|$. This requires to distinguish the cases $\tilde{y}_x > 0$ and $\tilde{y}_x < 0$. Since we are only interested in expanding winds in reasonable fluxsheets we can safely assume that the first case is always true. Then we find

$$A(u, y) = \frac{A_2}{e_{\text{pr}} Y \tilde{u}} \quad (7.57)$$

$$B(u, y) = B_3 - A_2 \frac{y \dot{e}_{\text{pr}} Y \tilde{u} + (\check{Y} e_{\text{pr}} + Y \check{e}_{\text{pr}}) y \tilde{\eta}}{e_{\text{pr}} Y \tilde{u}} \quad (7.58)$$

$$\dot{y} = \frac{\tilde{y}_x - y \dot{e}_{\text{pr}} Y \tilde{u} - (\check{Y} e_{\text{pr}} + Y \check{e}_{\text{pr}}) y \tilde{\eta}}{e_{\text{pr}} Y \tilde{u}}, \quad (7.59)$$

where $B_3(u, y) = B_2 + C \tilde{y}_x^{\alpha_{\text{cak}}}$ is just B_2 without the line acceleration term, which appears separately on the right hand side of Eq. 7.56. The deaccelerating solution ($\tilde{y}_x < 0$) differs from the result above only by a few signs. The auxiliary quantities of Eq. 7.56 are given by

$$\mu = \frac{\dot{\rho}}{\rho} = \frac{\partial_u |\nabla \eta|}{|\nabla \eta|} - \frac{\dot{\theta}}{\tan \theta} - \frac{\dot{x}}{x} \quad (7.60)$$

$$\gamma = \frac{\dot{\rho}}{\rho} = \frac{\partial_\eta |\nabla \eta|}{|\nabla \eta|} - \frac{\check{\theta}}{\tan \theta} - \frac{\check{x}}{x} - \frac{\check{Y}}{Y} + \frac{\check{\rho}_{\text{Ac}}}{\rho_{\text{Ac}}} \quad (7.61)$$

$$\frac{\check{F}}{F} = \frac{1}{2} \frac{\check{\rho}_{\text{Ac}}}{\rho_{\text{Ac}}} \quad (7.62)$$

$$M_{\text{p}}^2 = \frac{\rho_{\text{Ac}}}{\rho} M_{\text{pAc}}^2 = \frac{x \sin \theta}{x_{\text{Ac}} \sin \theta_{\text{Ac}}} \frac{y}{y_{\text{Ac}}} \frac{|\nabla \eta|_{\text{Ac}}}{|\nabla \eta|} \quad (7.63)$$

$$y_\phi = \frac{y_{\text{rot}}^2 - M_{\text{p}}^2 y_{\text{rot,Ac}}^2}{y_{\text{rot}} (1 - M_{\text{p}}^2)} \quad (7.64)$$

$$\frac{\partial y_\phi}{\partial M_{\text{p}}^2} = \frac{y_{\text{rot}}^2 - y_{\text{rot,Ac}}^2}{y_{\text{rot}} (1 - M_{\text{p}}^2)^2} \quad (7.65)$$

$$\dot{y}_\phi = \frac{y_{\text{rot}}^2 + M_{\text{p}}^2 y_{\text{rot,Ac}}^2}{y_{\text{rot}}^2 (1 - M_{\text{p}}^2)} \dot{y}_{\text{rot}} - \frac{\partial y_\phi}{\partial M_{\text{p}}^2} \mu M_{\text{p}}^2 \quad (7.66)$$

$$\tilde{y}_\phi = \frac{y_{\text{rot}}^2 + M_p^2 y_{\text{rot,Ac}}^2}{y_{\text{rot}}^2 (1 - M_p^2)} \tilde{y}_{\text{rot}} - \frac{\partial y_\phi}{\partial M_p^2} \gamma M_p^2 - \frac{2 y_{\text{rot,Ac}} \tilde{y}_{\text{rot,Ac}} M_p^2}{y_{\text{rot}} (1 - M_p^2)} \quad (7.67)$$

$$\hat{y}_\phi = \frac{\partial y_\phi}{\partial M_p^2} \frac{M_p^2}{y} \quad (7.68)$$

$$C(u, y) = \dot{x} \frac{\bar{C}}{x^2} \left(\frac{xy \sin \theta}{v_{\text{th}} |\nabla \eta|} \right)^{\alpha_{\text{cak}}} \quad (7.69)$$

$$\bar{C} = k_{\text{cak}} \Gamma \left(\frac{v_* |\nabla \eta|_{\text{Ac}}}{\kappa_{\text{Th}} r_* x_{\text{Ac}} \sin \theta_{\text{Ac}} y_{\text{Ac}} \rho_{\text{Ac}}} \right)^{\alpha_{\text{cak}}} \quad (7.70)$$

7.5 The transverse force component

The model developed in this chapter so far allows us to compute the wind in a fluxsheet of predefined shape. This is not very satisfying, because if we choose by chance a fluxsheet whose shape differs too much from the real shape we will get wind solutions without physical meaning. On the other hand the numerical effort for finding the shape of the fluxsheet and the wind solution simultaneously is much greater. In this case we have essentially a 2-dimensional problem. The compromise between these two extreme alternatives is to assume a priori a shape for the fluxsheet, to calculate the wind solution and finally to use the transverse component of the Euler equation to check whether we have chosen a reasonable shape of the fluxsheet. These two steps could even be iterated to get a consistent overall solution. Alternatively we could use the tangential and the transverse component of the Euler equation to find the shape of the fluxsheet and the wind velocity inside the fluxsheet simultaneously, while we integrate from the stellar surface outward. The difficulty to pass through all three critical points on the way would make a completely new computer code necessary. And it would not be clear from the beginning, whether this concept would work in the numerical praxis. For our initial calculations we choose a less ambitious approach by specifying shape of the fluxsheet a priori. This allows us to use our code for the equatorial wind with few modifications. Afterwards we use the transverse component of the Euler equation to check, whether the chosen shape for the fluxsheet was reasonable. This allows us to explore the raw shape of the real fluxsheet and leads to a much higher confidence in our solutions. For this approach we need a dimensionless form of the transverse component of the Euler equation.

We start our derivation from the Euler equation (Eq. 4.2), whose poloidal component (Eq. 7.42) we used to derive our wind equation. If we choose the right fluxsheet, the transverse component of Eq. 4.2

$$0 = \Delta g_t \equiv \mathbf{e}_t \cdot \left[(\mathbf{v} \cdot \nabla) \mathbf{v} + \frac{\nabla P}{\rho} + \nabla \Phi - \mathbf{g}_{\text{rad}} \right] + \left(\mathbf{e}_t \times \frac{\mathbf{B}}{4\pi\rho} \right) \cdot (\nabla \times \mathbf{B}) \quad (7.71)$$

with

$$\mathbf{e}_t = e_{p\theta} \mathbf{e}_r - e_{pr} \mathbf{e}_\theta \quad (7.72)$$

should be fulfilled, too. But in general we do not know the exact shape of the real fluxsheet. Therefore Δg_t will not be exactly zero for our solutions. In order to get an estimate how seriously Eq. 7.71 is violated we can compare Δg_t with the poloidal or transverse component of $(\mathbf{v} \cdot \nabla) \mathbf{v}$. Therefore we use now the same MATHEMATICA code, we used for Eq. 7.43, to derive dimensionless versions of Δg_t and $(\mathbf{v} \cdot \nabla) \mathbf{v}$. We find for the dimensionless version of Δg_t

$$\Delta a_t = \frac{r_*}{v_*^2} [\Delta g_t - \mathbf{e}_p \cdot ((\mathbf{v} \cdot \nabla) \mathbf{v})] \quad (7.73)$$

$$= A_4(u, y) \dot{y} + B_4(u, y, \dot{y}) + \Delta b_t \quad (7.74)$$

with

$$A_4 = - \left(e_{p\theta} \tilde{u} - \frac{e_{pr} \tilde{u}}{x} \right) \left[\frac{y_s^2}{y} - \frac{\bar{y}_\phi}{M_p^2} \left(\hat{y}_\phi - \frac{\bar{y}_\phi}{y} \right) \right] \quad (7.75)$$

$$B_4 = \left(e_{p\theta} \tilde{u} - \frac{e_{pr} \tilde{u}}{x} \right) \left[\frac{\dot{\rho}}{\rho} y_s^2 + \partial_u y_s^2 + \frac{\bar{y}_\phi}{M_p^2} \left(\frac{\dot{\rho}}{\rho} \bar{y}_\phi + \dot{y}_\phi \right) + \frac{y^2 Y^2 \dot{\rho}}{M_p^2 \rho} \right] + \left(e_{p\theta} \tilde{\eta} - \frac{e_{pr} \tilde{\eta}}{x} \right) \left[y_s^2 \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{Y}}{Y} \right) + \partial_\eta y_s^2 + \frac{\bar{y}_\phi}{M_p^2} \left(\tilde{y}_\phi - \tilde{\omega} x \sin \theta + \bar{y}_\phi \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{Y}}{Y} - \frac{\dot{F}}{F} \right) \right) + \frac{y^2 Y^2}{M_p^2} \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{F}}{F} \right) \right] + \left(\frac{e_{pr}}{x \tan \theta} - \frac{e_{p\theta}}{x} \right) \times$$

$$\begin{aligned} & \frac{\bar{y}_\phi}{M_p^2} (y_\phi - 2\bar{y}_\phi) + e_{p\theta} \left(\frac{1}{x^2} - a_{\text{rad}}(u, y, \dot{y}) \right) + \\ & \frac{y^2 Y^2}{M_p^2} \left(\ddot{e}_{p\theta} \tilde{\eta} + \dot{e}_{p\theta} \tilde{u} - \frac{\ddot{e}_{pr} \tilde{\eta} + \dot{e}_{pr} \tilde{u}}{x} + \frac{e_{p\theta}}{x} \right). \end{aligned} \quad (7.76)$$

For the tangential and transverse components of $(\mathbf{v} \cdot \nabla) \mathbf{v}$ we find

$$\Delta b_p = \frac{r_*}{v_*^2} \mathbf{e}_p \cdot ((\mathbf{v} \cdot \nabla) \mathbf{v}) \quad (7.77)$$

$$\begin{aligned} &= \left(e_{pr} \tilde{u} + \frac{e_{p\theta} \tilde{u}}{x} \right) y \dot{y} Y^2 + \left(e_{pr} \tilde{\eta} + \frac{e_{p\theta} \tilde{\eta}}{x} \right) y^2 Y \ddot{Y} - \\ & \left(\frac{e_{pr}}{x} + \frac{e_{p\theta}}{x \tan \theta} \right) y_\phi^2 \end{aligned} \quad (7.78)$$

$$\Delta b_t = \frac{r_*}{v_*^2} \mathbf{e}_t \cdot ((\mathbf{v} \cdot \nabla) \mathbf{v}) \quad (7.79)$$

$$\begin{aligned} &= \left(\frac{e_{pr}}{x \tan \theta} - \frac{e_{p\theta}}{x} \right) y_\phi^2 - y^2 Y^2 \left[(\ddot{e}_{p\theta} e_{pr} - \ddot{e}_{pr} e_{p\theta}) \left(e_{pr} \tilde{\eta} + \frac{e_{p\theta} \tilde{\eta}}{x} \right) + \right. \\ & \left. (\dot{e}_{p\theta} e_{pr} - \dot{e}_{pr} e_{p\theta}) \left(e_{pr} \tilde{u} + \frac{e_{p\theta} \tilde{u}}{x} \right) + \frac{e_{p\theta}}{x} \right]. \end{aligned} \quad (7.80)$$

Now we can use $|\Delta a_t / \Delta b_t|$ as relative measure how much the transverse component of the Euler equation is violated. But in order to estimate how relevant this violation is for the overall solution we should compare the transverse component of the Euler equation with the tangential component. This is given by the quantity $|\Delta a_t / \Delta b_p|$.

7.6 First numerical models

In this section we show some initial calculations, which try to develop further some ideas of Poe et al. [62] for winds from Wolf-Rayet stars. They developed a wind model for Wolf-Rayet stars based on the assumption that a fast and thin polar wind, driven only by the CAK line force, is responsible for the high observed terminal velocities. In the equatorial plane they assumed a thick and slow wind, additionally driven by a rotating magnetic field. Here they used a model similar to ours. This wind should be responsible for the high radio flux, which is otherwise explained as large spherical mass loss. Although this model is theoretically appealing it was ruled out as general concept for Wolf-Rayet stars by observations which showed that these stars in general do not have a strong density gradient between the polar and equatorial regions [65, 66]. In this section we want to argue that the model of Poe et al. might be modified to fit this observational fact. The basic idea is that the fluxsheets are bent towards the poles and not towards the equator. The latter is assumed in the wind compressed zone and disk models [12]. These models assume a nonmagnetic but rotating wind. In this case the centrifugal force will cause the deviation from radial outflow. But if we introduce a significantly strong magnetic field, the Lorentz force will dominate the centrifugal force. From the physics of jets we know that a rotating magnetic field can very efficiently collimate polar outflows. Additionally Owocki et al. have shown that the radiation force has a strong non-radial component [57]. This will even enhance the effect of the Lorentz force described in this section. For simplicity we do not include this radiation effect in our calculation at the current stage. In any case the equatorial outflow will automatically be dispersed. This will have several consequences: (1) The wind density in the polar region will be enhanced due to the geometrical compression. (2) The terminal wind velocity in the polar region will be reduced due to the fact that the polar fluxtube is collimated in the supersonic region. The reduced terminal wind velocity increases the polar wind density as well. (3) Exact the opposite happens in the equatorial region. There the terminal wind velocity is increased and the density is decreased. This reduces or maybe even eliminates the discrepancies between the polar and the equatorial wind predicted by the model of Poe et al. and criticized by the observations of Schulte-Ladbeck et al. [65, 66].

For our numerical models we use here the “Wolf-Rayet test model” of Poe et alii. This model star has a mass of $M = 13M_\odot$ and a luminosity of $L = 3 \times 10^5 L_\odot$. For the equatorial radius we use a preliminary value of $R = 5R_\odot$ for the base of the wind. For strong winds (high rotation rate and strong magnetic field) this will lead approximately to a radius of $8R_\odot$ for $\tau_{\text{es}} = 1$ as used by Poe et alii. For the CAK parameter we choose $\alpha_{\text{cak}} = 0.61$ and $k_{\text{cak}} = 0.18$. The electron scattering opacity for an Wolf-Rayet star $\kappa_{\text{Th}} = 0.2 \text{ cm}^2/\text{g}$ due to the missing hydrogen in the wind. For the wind temperature we choose a value of $T = 20000 \text{ K}$. Poe et al. quote a mass loss rate of $\dot{M}_{\text{obs}} = 3 \times 10^{-5} M_\odot/\text{yr}$ and a terminal velocity of $v_{\infty, \text{obs}} = 2900 \text{ km/s}$ as observational results for the wind. These values should be directly or indirectly be explained.

Table 7.1: Equatorial wind models for the Wolf-Rayet test star without any extra wind compression or dilution ($a(u) = 1$).

Our wind equations contain the necessary terms to include differential rotation. And from our sun we know that stars can rotate differential. It might even be that differential rotation is the normal case for stars. Nevertheless we limit our discussion here to the case where the rotation rate of the star does not depend on latitude ($\tilde{\omega} = 0$) to reduce the number of free parameters in this initial analysis.

We can not reproduce the numerical results of Poe et al. exactly as we did for the O star models of Friend & MacGregor [20] in Chap. 5, because for simplicity we do not include the correction for the finite disk of the star [16, Eq. 50] in our equation at the current stage. Additionally Poe et al. do not print their wind equations explicitly. Including the finite disk correction will be necessary later when this model is developed further to explain Wolf-Rayet star winds quantitatively.

In a first step we calculated a set of equatorial wind models to get a first feeling for the dependence of $\dot{M}$ and v_{∞} on the wind parameter α_{rot} and B_{p0} . These calculations confirmed the results of Poe et al. that in a simple equatorial model we need a high rotation rate to explain the high mass loss rates and a very strong magnetic field to explain the high terminal velocities. We agree with Poe et al. that such a model would be ruled out by the spin-down problem.

The next step is to check that the magnetic force really collimates the fluxsheets towards the poles. To check this we calculated wind models for a set of non-equatorial fluxsheets. For these first calculations we used fluxsheets which were not bent (Fig. 7.4). This fluxsheets configuration would be expected for a nonrotating star. This fluxsheet configuration is mathematically given by

$$x(u, \eta) = \frac{\sqrt{1 + \eta^2}}{u} \quad (7.81)$$

$$\theta(u, \eta) = \text{arccot} \eta. \quad (7.82)$$

It should be mentioned that in this special case the wind equation (Eq. 7.56) becomes independent of $\tilde{Y}$, $\tilde{\rho}$, $\tilde{\omega}$ and $\tilde{F}$, because $\dot{x}\tilde{\eta} + \dot{\theta}\tilde{\eta}$ is always zero. But this is not true for the transverse force component. We calculated 11 models with η between 0 and 1 covering an lateral angle of θ between 90 and 45 degrees. We used a magnetic field of 1000 G and a rotation rate of $\alpha_{\text{rot}} = 0.95$. The latter is more extreme than the values given in Tab. 7.1 and Fig. 7.3. But the idea of this section is to propose a model with a strong equatorial wind due to rapid rotation. The magnetic field should be moderate, so that we do not have a spin-down problem. But it should be strong enough to spread the mainly equatorial mass outflow of the whole hemisphere, so that this model is not ruled out by the lack of observed polarisation. As reference radius for the terminal velocity we chose $100R$. For comparison with observation this reference radius should not be chosen too large, because the P-Cygni profiles are not too

Figure 7.3: shows $\dot{M}$ versus v_{∞} for the models from Tab. 7.1. The solid lines connect models with a constant value of α_{rot} . The dotted lines connect models with a constant magnetic field strength. Additionally the observed (+) values and the values for the nonrotating, nonmagnetic case (CAK) are shown. Rotation basically increases the mass loss rate. While the magnetic field basically increases the terminal velocity rate.

Figure 7.4: shows the meridional plane (r, θ or u, η). The fluxsheets start from the stellar surface and extend straight outwards. This fluxsheet geometry was used for our first calculations which should prove that the fluxsheets are actually collimated towards the poles. The star is oblate due to its rotation ($\alpha_{\text{rot}} = 0.95$).

Figure 7.5: shows Δa_t as defined in Eq. 7.73 for the $\eta = 1$ solution from Tab. 7.2.

far away from the star. The next important step is to check whether the fluxsheets should now be bent towards the polar axis or towards the equatorial plane. For the $\eta = 1$ ($\theta = 45^\circ$) solution we evaluated Δa_t , Δb_t , and Δb_p as defined in Sect. 7.5. The function $Y(\eta)$ is fitted to the wind velocities in the different fluxsheets at $r = 2R$. The result is plotted in Figs. 7.5–7.7. The singularity we see in Fig. 7.5 is due to the Alfvénic point, where we yet do not use all side conditions to keep the transverse force finite. If we mentally subtract the singularity from the plot, we see that Δa_t is negative everywhere, and that we get the strongest transverse force component close to the stellar surface. In Fig. 7.6 we see the inertial contributions to the transverse Euler equations. Since the fluxsheet is not bent we have only the transverse component of the centrifugal force here, which of course is directed towards the equatorial plane. The centrifugal contribution has the opposite sign than the magnetic contribution from Fig. 7.5. And it is close to the stellar surface more than an order of magnitude smaller. The same is true for the poloidal component of the inertial force. We can therefore conclude from here that the fluxsheets should be strongly bent towards the polar axis. We find the same result for the $\eta = 0.1$ fluxsheet. Although the force towards the polar axis is not so strong close to the equatorial plane. The next step is now to calculate wind solutions for fluxsheets which are bent towards the polar axis. As an first approximation for the fluxsheets we choose the fluxsheet shape shown in Fig. 7.8. We get again a one parameter family of fluxsheets with η as parameter. The additional parameters λ and δ are constant for all fluxsheets in a stellar wind model. The motivation for this nonobvious choice was to produce fluxsheets which are bent towards the polar axis close to the star and rather straight far away from the star, where the magnetic field is weak. Our fluxsheets start

Figure 7.6: shows Δb_t as defined in Eq. 7.79 for the $\eta = 1$ solution form Tab. 7.2.

Figure 7.7: shows Δb_p as defined in Eq. 7.77 for the $\eta = 1$ solution form Tab. 7.2.

Figure 7.8: shows geometry of the curved fluxsheets used in this chapter.

with an inclination of $\theta = \text{arccot } \eta$ for $x \rightarrow 0$ ($u \gg \delta/2$) and have an inclination of $\eta(1 + \lambda\pi/2)$ at $x \rightarrow \infty$ ($u \ll \delta/2$). So λ controls how strong the fluxsheets are bent. While δ controls how fast they are bent. For $\lambda = 0$ these fluxsheets reduce to the straight fluxsheets used previously in this section. And for $\lambda = \eta = 0$ we obtain the equatorial fluxsheet used everywhere in this thesis. The equatorial fluxsheet should always be straight due to the symmetry between northern and southern hemisphere.

We started our analysis of bent fluxsheets trying to find solutions with three critical points. But we found that the solutions extend only beyond the outer critical point if the fluxsheets are nearly straight. A numerical analysis of the solution around the outer critical points showed that the third condition for the critical point (Eq. B.8) is not fulfilled with the necessary numerical precision. This might have two reasons. (1) The numerical roundoff errors in the formulas for the critical point are too large. Therefore the root finding algorithm of our code can not find the position of the outer critical point with the required precision. This would require an improvement of our numerical code in order to reduce roundoff errors. (2) There might be no point on our fluxsheet where all three conditions for the outer critical point are fulfilled. This would require a deeper mathematical analysis of our wind equation. It might be that we can derive from this problem further conditions for the shape of fluxsheets which have a complete wind solution. For this point see also Appendix B. Due to this problem we calculated few initial wind solutions without the outer critical point analogous to our models in Chap. 5. But these models still have fairly straight fluxsheets. The results are still too few and inconsistent to be published here. But we showed here that the non-equatorial fluxsheets are indeed bended towards the poles. Future numerical computations will complete the picture we sketched here and show how strong the effect of the bent fluxsheets really is.

Chapter 8

Conclusions

In this thesis we analyzed new aspects in the theory of magnetic winds from massive stars. This work was motivated by the fact that we have many indirect hints for the existence of a significant magnetic field in the wind of massive stars [9], although the magnetic field is not accessible for direct observation yet [25]. The development of the theory is still at a very early stage. Therefore we can not yet produce models, which allow to describe and understand in detail the complex structure of the winds from massive stars we know from observation. But in this thesis we present two new and important components in the theory of magnetic winds from massive stars. It is important to recognize that both components are not optional. Both effects are automatically present without further conditions, if the star rotates with a significant magnetic field.

In Chap. 6 we analyzed, in the linear limit, the evolution of wind instabilities in magnetic winds. The foundation for this analysis is the well known instability of the line driving mechanism. This instability has been intensively studied [52, 53, 54, 55, 56]. And it seems that this instability can explain some details in the spectra of massive stars. But in spite of initial hopes [36] no way was found how these waves can help to solve the basic wind momentum problem in many of these stars, especially Wolf-Rayet stars. We showed in our analysis that the magnetic field is the missing key. It has a strong influence of the behavior of the waves resulting from this instability. In the nonmagnetic case the waves are dominantly running inward, leading to reverse shocks. If a significant magnetic field is present, the waves are running dominantly outward, leading to forward shocks. These forward shocks will contain layers of material which have a much higher velocity than the terminal velocity found in stationary and smooth wind models. This is an important contribution to the explanation of the observations. Stationary wind models need a very high magnetic field to produce a high terminal velocity. Such a high magnetic field would cause a spin-down problem, which is easily avoided in our wind models with waves. Additionally our waves produce a higher *observed* mass loss rate by feigning a higher terminal velocity and a higher wind density through clumping. This helps to overcome the wind problem in Wolf-Rayet stars as well.

Our second model, the bending of the non-equatorial fluxsheets towards the poles, is a direct and unavoidable consequence of significant rotation and magnetic field strength. This effect is a ideal extension to our first model, because its results lead into the same direction. We showed that the non-equatorial fluxsheets are bent towards the poles. This has several consequences. Due to the extension of the flux cross section in the equatorial region we will get an even higher terminal velocity, because the wind is supersonic except very close to the star. The wind material will be spread more equally over all lateral regions. This will avoid the problems which previous models [62] had with the unobserved polarization of the stellar light [66].

Previous wind models had to use rather slow rotation and rather strong magnetic fields to produce the high observed terminal velocities and to avoid conflicts with the not observed polarization of the stellar light. But such models lead to a rapid spin-down. We can now avoid this using a wind model with rapid rotation and moderate magnetic fields. In this case we have strong mass loss combined with a sufficiently small angular momentum loss. In such a model the mass loss will be concentrated in the equatorial regions. But our bent fluxsheets will distribute the wind material in the polar regions as well, so that we can avoid the polarization problem. Additionally our outward running waves will reproduce the high observed terminal velocities without requiring a stronger magnetic field. These two models in combination help a lot to fit theoretical models for magnetic winds to the observations.

Nevertheless we are not at the end of the development. We are only at the beginning. And there is still a lot of interesting work to do. The next, direct step should be a deeper mathematical and numerical analysis of our fluxsheet model in order to complete this work. In general both of our models can be improved. For our analysis of waves in magnetic winds the next step is to look at the nonlinear case and to demonstrate that our predictions for the behavior of magnetic shock fronts are correct. This work could produce quantitative predictions for

the X-ray emission, for the nonthermal radio emission, and for the cosmic ray emission. This would improve our understanding of the microphysics of these winds. Our fluxsheet model can be improved beyond the steps already mentioned here and in Chap. 7 in two directions: (1) A more detailed description of the radiation driving mechanism can give a better understanding of optical thick winds [23]. And the non-radial component of the radiation force can bend the fluxsheets even more towards the poles [57]. It should therefore be included in our model. This might be important in order to show, that the wind material is really equally distributed around the star, and we therefore see no polarization. (2) The second major direction in the future development of the fluxsheet model is the implementation of a real two dimensional treatment of the MHD equations to get a better understanding of the shape of the fluxsheets and of the large scale structure of the wind.

Another large area of future work is the application of the fluxsheet model to other winds. On purpose we did not integrate a specific geometrical shape of the fluxsheets into the fluxsheet model. With few modifications it is possible to use the model with a different fluxsheet geometry. This allows e.g. to model the wind from accretion disks in young stellar objects or in AGNs. This opens a wide range of future projects.

Thus at the end of this thesis we have the exciting situation of science: Answer one question, and you find three new ones!

Appendix A

The equatorial wind as limiting case

In this appendix we derive the equations for the equatorial wind from Chap. 4 as a limiting case of the wind equations from Chap. 7. This is an important consistency check for the new model. Additionally it allows to relate results calculated with the equations of Chap. 4 to results calculated with the equations of Chap. 7. The equations of Chap. 4 can be obtained by using the fluxsheet shape functions

$$x(u, \eta) = \frac{1}{u} \quad (\text{A.1})$$

$$\theta(u, \eta) = \arccos[a(u)\eta], \quad (\text{A.2})$$

where $a(u)$ is the area function for the equatorial fluxsheet we have introduced in Chap. 4. The equatorial fluxsheet is specified by

$$\eta = 0. \quad (\text{A.3})$$

The symmetry between northern and southern hemisphere requires that our self-similarity functions $\check{Y}$, $\check{F}$, $\check{\omega}$, $\check{\rho}_{\text{Ac}}$, and $\check{B}_{\text{pAc}}$ vanish in the equatorial plane. For Y we choose 1 in the equatorial plane. We find then for the geometry expressions

$$\dot{x} = -\frac{1}{u^2} \quad (\text{A.4})$$

$$\tilde{u} = -u^2 \quad (\text{A.5})$$

$$\check{\theta} = -a \quad (\text{A.6})$$

$$|\nabla\eta| = \frac{u}{ar_*} \quad (\text{A.7})$$

$$\partial_u |\nabla\eta| = \frac{1}{ar_*} \left(1 - \frac{u\dot{a}}{a} \right) \quad (\text{A.8})$$

$$s = -1 \quad (\text{A.9})$$

$$e_{\text{pr}} = 1 \quad (\text{A.10})$$

$$e_{\text{p}\theta} = 0. \quad (\text{A.11})$$

All other relevant geometrical quantities are zero. We find then for the auxiliary quantities (Eqs. 7.55, 7.60–7.70)

$$|\tilde{y}_x| = -u^2 \dot{y} \quad (\text{A.12})$$

$$\frac{\dot{\rho}}{\rho} = \frac{2}{u} - \frac{\dot{a}}{a} \quad (\text{A.13})$$

$$\frac{\check{\rho}}{\rho} = 0 \quad (\text{A.14})$$

$$M_{\text{p}}^2 = M_{\text{Ar}}^2 = \frac{u_{\text{Ac}}^2}{u^2} \frac{y}{y_{\text{Ac}}} \frac{a}{a_{\text{Ac}}} = \frac{1}{1 - U_M} \quad (\text{A.15})$$

$$y_{\phi} = \omega \frac{M_{\text{p}}^2 - \frac{x^2}{x_{\text{Ac}}^2} x_{\text{Ac}}^2}{M_{\text{p}}^2 - 1} \frac{1}{x} \quad (\text{A.16})$$

$$= y_{\text{rot}} \frac{\frac{x_{\text{Ac}}^2}{x^2} M_{\text{Ar}}^2 - 1}{M_{\text{Ar}}^2 - 1} \quad (\text{A.17})$$

$$= y_{\text{rot}} \frac{U_M - U_{\epsilon}}{U_M} \quad (\text{A.18})$$

$$\frac{\partial y_\phi}{\partial M_p^2} = y_{\text{rot}} \frac{1 - \frac{x_{\text{Ac}}^2}{x^2}}{(1 - M_{\text{Ar}}^2)^2} \quad (\text{A.19})$$

$$= \frac{y_{\text{rot}}}{M_{\text{Ar}}^4} \frac{U_\epsilon}{U_M^2} \quad (\text{A.20})$$

$$\dot{y}_\phi = -\frac{\omega}{u^2} \frac{1 + M_{\text{Ar}}^2 \frac{x_{\text{Ac}}^2}{x^2}}{1 - M_{\text{Ar}}^2} - \frac{\partial y_\phi}{\partial M_p^2} \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) M_{\text{Ar}}^2 \quad (\text{A.21})$$

$$= \frac{y_{\text{rot}}}{u} \left[\frac{2 - U_\epsilon - U_M}{U_M} - \frac{1}{M_{\text{Ar}}^2} \frac{U_\epsilon}{U_M^2} \left(2 - \frac{u\dot{a}}{a} \right) \right] \quad (\text{A.22})$$

$$\ddot{y}_\phi = 0 \quad (\text{A.23})$$

$$\hat{y}_\phi = \frac{y_{\text{rot}}}{y} \frac{U_\epsilon}{U_M^2} \frac{1}{M_{\text{Ar}}^2} \quad (\text{A.24})$$

$$= \frac{y_{\text{rot}}}{y} \frac{U_\epsilon}{U_M^2} (1 - U_M) \quad (\text{A.25})$$

$$C |\tilde{y}_x|^{\alpha_{\text{cak}}} = -k_{\text{cak}} \Gamma \left(\frac{4\pi GM}{\kappa_{\text{Th}} v_{\text{th}} \dot{M}} \right)^{\alpha_{\text{cak}}} (-y\dot{y}a)^{\alpha_{\text{cak}}} \quad (\text{A.26})$$

$$\bar{y}_\phi = y_\phi - y_{\text{rot}} \quad (\text{A.27})$$

$$= -y_{\text{rot}} \frac{U_\epsilon}{U_M}, \quad (\text{A.28})$$

where we have used $y_{\text{rot}} = \omega/u$ and $Q = y_0/M_{\text{Ar}0}^2$. We can now express Eq. 7.56 with

$$A\tilde{y}_x = A_2\dot{y} \quad (\text{A.29})$$

$$= \dot{y} \left[y - \frac{y_s^2}{y} - y_{\text{rot}} \frac{U_\epsilon}{U_M} (1 - U_M) \left[\frac{y_{\text{rot}}}{y} \frac{U_\epsilon}{U_M} \left(\frac{1}{U_M} - 1 \right) + \frac{y_{\text{rot}}}{y} \frac{U_\epsilon}{U_M} \right] \right] \quad (\text{A.30})$$

$$= \dot{y} \left[y - \frac{y_s^2}{y} - (1 - U_M) \frac{y_{\text{rot}}^2}{y} \frac{U_\epsilon^2}{U_M^3} \right] \quad (\text{A.31})$$

$$= y\dot{y} \left[1 - \frac{y_s^2}{y^2} - \frac{y_{\text{rot}0}^2}{y^2} \frac{Q}{y} \frac{U_\epsilon^2}{U_M^3} \frac{a_0}{a} \right] \quad (\text{A.32})$$

$$B = B_2 \quad (\text{A.33})$$

$$= -1 + \Gamma + y_s^2 \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) + \partial_u y_s^2 - y_{\text{rot}} \frac{U_\epsilon}{U_M} (1 - U_M) \times \left[-y_{\text{rot}} \frac{U_\epsilon}{U_M} \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) + \frac{y_{\text{rot}}}{u} \left[\frac{2 - U_\epsilon - U_M}{U_M} - \frac{1}{M_{\text{Ar}}^2} \frac{U_\epsilon}{U_M^2} \left(2 - \frac{u\dot{a}}{a} \right) \right] \right] + \frac{1}{u} \left[-y_{\text{rot}} \frac{U_\epsilon}{U_M} (1 - U_M) \times \left(y_{\text{rot}} + y_{\text{rot}} \frac{U_\epsilon}{U_M} \right) + y_{\text{rot}}^2 \left(1 - \frac{U_\epsilon}{U_M} \right)^2 \right] \quad (\text{A.34})$$

$$= -1 + \Gamma + y_s^2 \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) + \partial_u y_s^2 + \frac{y_{\text{rot}}^2}{u U_M^2} [-2U_\epsilon(1 - U_M) + (U_\epsilon - U_M)^2 + \frac{U_\epsilon^2}{U_M} (1 - U_M) \left(2 - \frac{u\dot{a}}{a} \right)] \quad (\text{A.35})$$

$$= -1 + \Gamma + y_s^2 \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) + \partial_u y_s^2 - \frac{y_{\text{rot}}^2}{u U_M^2} (U_M - U_\epsilon) \times \left[-2 \frac{U_\epsilon}{U_M} (1 - U_M) + U_M - U_\epsilon \right] - \frac{y_{\text{rot}}^2}{U_M^2} \frac{U_\epsilon^2}{U_M} (1 - U_M) \frac{\dot{a}}{a} \quad (\text{A.36})$$

$$= -1 + \Gamma + y_s^2 \left(\frac{2}{u} - \frac{\dot{a}}{a} \right) + \partial_u y_s^2 - \frac{\lambda}{U_M^2} \frac{u}{u_0} \left[\epsilon - \frac{Q}{y} \frac{a_0}{a} \right] \times \left[\left(2 \frac{U_\epsilon}{U_M} + 1 \right) \frac{Q}{y} \frac{a_0}{a} - \epsilon \right] - \frac{\lambda}{U_M^2} \frac{u_0}{u} \frac{U_\epsilon^2}{U_M} \frac{Q}{y} \frac{a_0 u \dot{a}}{a^2}, \quad (\text{A.37})$$

where we have used $\lambda = \omega^2/u_0^3$. This result (Eqs. 7.56, A.26, A.32 & A.37) reproduces our results from chapter 5 (Eqs. 5.1–5.4). It might now appear that the equatorial version of the wind equations is superfluous since we have the general version. But they were an important step in the development of the generalized model. Additionally they are much simpler, so that their numerical implementation is faster and more robust against numerical roundoff errors. Therefore it is useful to start numerical computations with the equatorial wind equations.

Appendix B

Numerical considerations

Before we can integrate Eq. 7.56 to find a unique wind solution, we have to specify some numerical parameters: (1) We have to describe the geometrical shape of the fluxsheet by specifying r_* , $x(u, \eta)$, and $\theta(u, \eta)$. This defines $|\nabla\eta|$ as well. (2) The next step is to specify the self-similarity functions $Y(\eta)$ and $\rho_{Ac}(\eta)$. These functions have to be guessed for the first calculations. Then we can derive them from previous calculations until we get a self-consistent combination of self-similarity functions and wind solutions. (3) The star itself is described by its luminosity L_* , its mass M , and its equatorial radius R_{eq} , its (equatorial) magnetic field B_{p0Eq} , and its equatorial rotation rate $\alpha_{rot,eq}$. (4) The physics in the wind depends on the CAK parameters α_{cak} , k_{cak} and on the temperature stratification $T(u)$. All models presented in this thesis assume an isothermal wind. (5) Finally some of these quantities may depend on latitude. For all numerical models presented here we ignore differential rotation $\alpha_{rot}(\eta) = \alpha_{rot,eq}$ and a lateral dependence of the magnetic field. But the lateral dependence of the stellar radius can not be ignored. Some wind models in this thesis have a rather high rotation rate, which will lead to an oblate star. Without going deep into the theory of stellar structure we can describe the stellar surface as an equipotential surface of

$$\Phi(r, \theta) = -\frac{GM}{r} - \frac{\Omega^2 r^2 \sin^2 \theta}{2}. \quad (B.1)$$

The radius $R(\eta)$ for the base of the wind is given by the point where the fluxsheets intersects the stellar surface. We can find this point by solving

$$\Phi(r_* x(u_0(\eta), \eta), \theta(u_0(\eta), \eta)) = \Phi\left(R_{eq}, \frac{\pi}{2}\right) \quad (B.2)$$

for $u_0(\eta)$. Finally we have to specify eigenvalues as in the equatorial case. We chose again the position of the Alfvénic point u_{Ac} and the approximate mass loss rate (Eq. 7.37). Using

$$B_{pAc} = B_{p0} \frac{|\nabla\eta|_{Ac}}{|\nabla\eta|_0} \frac{x_0 \sin \theta_0}{x_{Ac} \sin \theta_{Ac}} \quad (B.3)$$

$$y_{Ac} = \frac{1}{v_*} \frac{B_{pAc}}{\sqrt{4\pi\rho_{Ac}}} \quad (B.4)$$

the wind velocity y_{Ac} and the density ρ_{Ac} at the Alfvénic point can be found.

In the case of a cold wind ($v_s = 0$) we integrate Eq. 7.56 from Alfvénic critical point u_{Ac} to the base of the wind u_0 and to infinity. We can obtain u_{Ac} by fitting a reasonable initial wind velocity v_0 at the base of the wind.

In the case of a warm wind ($v_s > 0$) we integrate from the inner critical point to the base of the wind and to the Alfvénic critical point and from the outer critical point to the Alfvénic critical point and to infinity. We can now fit the initial wind velocity at the base of the wind and a continuous wind acceleration at the Alfvénic critical point. These two conditions allow to find u_{Ac} and the mass loss rate.

One important point has yet not been taken into account properly. The plot for the transverse component of the magnetic force shows a singularity at the Alfvénic point. This is of course not physical. The reason for this is the uncompensated $(1 - M_p^2)^{-1}$ term in the formulas for the various derivatives of y_ϕ (Eqs. 7.64–7.67). These derivatives enter the wind equation (Eq. 7.56) and the equation for the transverse forces (Eq. 7.73). The wind equation has a singularity at the Alfvénic point. But this is already known from the equatorial theory. The coordinates of the Alfvénic point are chosen so that we get a solution with finite y and y_ϕ at the Alfvénic point. But nevertheless this is a problem which has to be fixed before really reliable results for winds in bended fluxsheets can be calculated. We might derive an additional condition for the wind solution at the Alfvénic point from the proper treatment of the transverse Euler equation.

Another challenging point is the computation of the inner and outer critical points. The wind equation derived in this chapter is much more complicated than the equatorial equations derived in the previous chapters. We derive here the equations for the CAK-type critical points in the non-equatorial wind using the same argument as in the case of the equatorial wind. At the CAK-type critical points we have

$$0 = A\tilde{y}_x + B - C\tilde{y}_x^{\alpha_{\text{cak}}} \quad (\text{B.5})$$

$$0 = A - \alpha C\tilde{y}_x^{\alpha_{\text{cak}}-1} \quad (\text{B.6})$$

$$0 = \frac{d}{du} (A\tilde{y}_x + B - C\tilde{y}_x^{\alpha_{\text{cak}}}). \quad (\text{B.7})$$

With Eq. B.6 $\tilde{y}$ can be eliminated from Eq. B.7 leading to

$$0 = [\dot{A} + \dot{y}\hat{A}] \tilde{y}_x + [\dot{B} + \dot{y}\hat{B}] - [\dot{C} + \dot{y}\hat{C}] \tilde{y}_x^{\alpha_{\text{cak}}}. \quad (\text{B.8})$$

Eqs. B.5, B.6 & B.8 form a set of three nonlinear equations with three unknowns: u , y , and $\dot{y}$. We can therefore expect at least locally unique solutions. Since these equations are very complicated and essentially non-algebraic, it is not possible to find an analytic solution. We use a numerical method based on Newton's algorithm. This algorithm requires the Jacobian matrix of the terms on the right hand sides of Eqs. B.5, B.6 & B.8 with respect to u , y , and $\dot{y}$. This requires the second derivatives of A , B , and C .

Since Eq. B.8 is very complicated it seems reasonable to evaluate the derivatives of A and B numerically. But we have to consider that the Jacobian matrix, which contains the second derivatives of A , B , and C , is even more complicated and requires certainly numerical evaluation. Tests have shown that evaluating the first and second derivatives of A , B , and C numerically causes severe numerical roundoff errors, which make it impossible to find the critical points. The reason is that numerical derivatives contain the difference of two nearly identical quantities. This leads to a loss of precision. In our case the situation is worse due to the fact that the right hand sides of Eqs. B.5, B.6 & B.8 vanish at the critical point as well. I.e. they are differences of nearly identical quantities close to the critical points. We control these problems by using quadruple precision for all numerical calculations. Additionally we use numerical derivatives only for the Jacobian matrix. Nevertheless our code has some times problems finding the outer critical point numerically. But it is not clear yet, whether this is an numerical or a mathematical problem. See Sect. 7.6 for more details. Finally it should be mentioned that in general a forth condition for the inner and outer critical point can be found. A 'perfect' wind solution should fulfill the transverse Euler equation everywhere. In this case we can demand that analogous to Eq. B.7 the total derivative of the transverse Euler equation with respect to u vanishes. Further details are discussed by Falcke [18, Sect. 5.3]. Our solutions do not obey the transverse Euler equation in general. Therefore we can not use this condition for our critical points.

The analytical expressions for the first derivatives of A , B , and C are given now. The formulas are rather complicated and offer certainly some space for simplifications.

$$\dot{A} = \left(\frac{\dot{A}_2}{A_2} - \frac{\dot{e}_{\text{pr}}}{e_{\text{pr}}} - \frac{\dot{\tilde{u}}}{\tilde{u}} \right) A \quad (\text{B.9})$$

$$\dot{A}_2 = A_2 \frac{\dot{\chi}}{\chi} + \chi \left[-\frac{\partial_u y_s^2}{y} + \varrho \left(\hat{y}_\phi - \frac{\dot{\hat{y}}_\phi}{y} \right) + \dot{\varrho} \left(\hat{y}_\phi - \frac{\bar{y}_\phi}{y} \right) \right] \quad (\text{B.10})$$

$$\hat{A} = \frac{\hat{A}_2}{e_{\text{pr}} Y \tilde{u}} \quad (\text{B.11})$$

$$= \frac{\chi}{e_{\text{pr}} Y \tilde{u}} \left[Y^2 + \frac{y_s^2}{y^2} + \varrho \left(\hat{y}_\phi - \frac{\hat{y}_\phi y - \bar{y}_\phi}{y^2} \right) + \hat{\varrho} \left(\hat{y}_\phi - \frac{\bar{y}_\phi}{y} \right) \right] \quad (\text{B.12})$$

$$\dot{B} = \dot{B}_3 - \dot{A}(y\dot{e}_{\text{pr}}Y\tilde{u} + (\tilde{Y}e_{\text{pr}} + Y\dot{e}_{\text{pr}})y\tilde{\eta}) - A(yY(\ddot{e}_{\text{pr}}\tilde{u} + \dot{e}_{\text{pr}}\dot{\tilde{u}} + \ddot{e}_{\text{pr}}\tilde{\eta} + \dot{e}_{\text{pr}}\dot{\tilde{\eta}}) + \tilde{Y}y(\dot{e}_{\text{pr}}\tilde{\eta} + e_{\text{pr}}\dot{\tilde{\eta}})) \quad (\text{B.13})$$

$$\begin{aligned} \dot{B}_3 = & \dot{\chi} [y_s^2\mu + \partial_u y_s^2 + \varrho(\mu\bar{y}_\phi + \dot{y}_\phi)] + \chi [\mu\partial_u y_s^2 + \dot{\mu}y_s^2 + \partial_u^2 y_s^2 + \\ & \dot{\varrho}(\mu\bar{y}_\phi + \dot{y}_\phi) + \varrho(\dot{\mu}\bar{y}_\phi + \mu\dot{\bar{y}}_\phi + \ddot{y}_\phi)] + \dot{\xi} [Y\tilde{Y}y^2 + \\ & y_s^2 \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{Y}}{Y} \right) + \partial_\eta y_s^2 + \varrho \left(\ddot{y}_\phi - \ddot{\omega}x \sin \theta + \hat{y}_\phi \frac{\dot{Y}}{Y} y + \right. \\ & \left. \bar{y}_\phi \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{Y}}{Y} - \frac{\dot{F}}{F} \right) \right)] + \xi \left[\partial_u y_s^2 \left(\frac{\dot{\rho}}{\rho} - \frac{\dot{Y}}{Y} \right) + y_s^2 \dot{\mu} + \partial_u \partial_\eta y_s^2 + \right. \end{aligned}$$

$$\begin{aligned}
& \dot{\varrho} \left(\check{y}_\phi - \check{\omega} x \sin \theta + \hat{y}_\phi \frac{\check{Y}}{Y} y + \bar{y}_\phi \left(\frac{\check{\rho}}{\rho} - \frac{\check{Y}}{Y} - \frac{\check{F}}{F} \right) \right) + \varrho \left(\dot{\check{y}}_\phi - \right. \\
& \left. \check{\omega} (\dot{x} \sin \theta + x \dot{\theta} \cos \theta) + \dot{\hat{y}}_\phi \frac{\check{Y}}{Y} y + \dot{\bar{y}}_\phi \left(\frac{\check{\rho}}{\rho} - \frac{\check{Y}}{Y} - \frac{\check{F}}{F} \right) + \bar{y}_\phi \dot{\mu} \right) - \\
& \left(\frac{\ddot{x}x - \dot{x}^2}{x^2} + \frac{\ddot{\theta}}{\tan \theta} - \frac{\dot{\theta}^2}{\sin^2 \theta} \right) [\varrho (x \sin \theta \omega - \bar{y}_\phi) + y_\phi^2] - \\
& \left(\frac{\dot{x}}{x} + \frac{\dot{\theta}}{\tan \theta} \right) [\dot{\varrho} (x \sin \theta \omega - \bar{y}_\phi) \\
& + \varrho \left(\omega (\dot{x} \sin \theta + x \cos \theta \dot{\theta}) - \dot{\bar{y}}_\phi \right) + 2y_\phi \dot{y}_\phi] + \\
& \frac{\ddot{x}x - 2\dot{x}^2}{x^3} (1 - \Gamma)
\end{aligned} \tag{B.14}$$

$$\begin{aligned}
\hat{B} &= \hat{B}_3 - \hat{A}(y \dot{e}_{pr} Y \tilde{u} + (\check{Y} e_{pr} + Y \check{e}_{pr}) y \tilde{\eta}) - \\
& A(\dot{e}_{pr} Y \tilde{u} + (\check{Y} e_{pr} + Y \check{e}_{pr}) \tilde{\eta})
\end{aligned} \tag{B.15}$$

$$\begin{aligned}
\hat{B}_3 &= \chi \left[\varrho \left(\mu \hat{y}_\phi + \dot{\hat{y}}_\phi \right) + \hat{\varrho} (\mu \bar{y}_\phi + \dot{\bar{y}}_\phi) \right] + \\
& \xi \left[2Y \check{Y} y + \hat{\varrho} \left(\check{y}_\phi - \check{\omega} x \sin \theta + \hat{y}_\phi \frac{\check{Y}}{Y} y + \bar{y}_\phi \left(\frac{\check{\rho}}{\rho} - \frac{\check{Y}}{Y} - \frac{\check{F}}{F} \right) \right) + \right. \\
& \left. \varrho \left(\hat{\hat{y}}_\phi + \frac{\check{Y}}{Y} (\hat{\hat{y}}_\phi y + \hat{\hat{y}}_\phi) + \hat{\hat{y}}_\phi \left(\frac{\check{\rho}}{\rho} - \frac{\check{Y}}{Y} - \frac{\check{F}}{F} \right) \right) \right] \\
& - \left(\frac{\dot{x}}{x} + \frac{\dot{\theta}}{\tan \theta} \right) [\hat{\varrho} (x \sin \theta \omega - \bar{y}_\phi) - \varrho \hat{y}_\phi + 2y_\phi \hat{y}_\phi]
\end{aligned} \tag{B.16}$$

$$\begin{aligned}
\dot{C} &= \left[\frac{\ddot{x}}{\dot{x}} + (\alpha_{\text{cak}} - 2) \frac{\dot{x}}{x} + \right. \\
& \left. \alpha_{\text{cak}} \left(\frac{\dot{\theta}}{\tan \theta} - \frac{\dot{v}_{\text{th}}}{v_{\text{th}}} - \frac{\partial_u |\nabla \eta|}{|\nabla \eta|} \right) \right] C
\end{aligned} \tag{B.17}$$

$$\hat{C} = \alpha_{\text{cak}} \frac{C}{y}. \tag{B.18}$$

For brevity we used the following auxiliary quantities

$$\chi = \dot{x} \tilde{u} + \dot{\theta} \tilde{u} \tag{B.19}$$

$$\dot{\chi} = \ddot{x} \tilde{u} + \dot{x} \dot{\tilde{u}} + \ddot{\theta} \tilde{u} + \dot{\theta} \dot{\tilde{u}} \tag{B.20}$$

$$\xi = \dot{x} \tilde{\eta} + \dot{\theta} \tilde{\eta} \tag{B.21}$$

$$\dot{\xi} = \ddot{x} \tilde{\eta} + \dot{x} \dot{\tilde{\eta}} + \ddot{\theta} \tilde{\eta} + \dot{\theta} \dot{\tilde{\eta}} \tag{B.22}$$

$$\varrho = \frac{\bar{y}_\phi}{M_p^2} \tag{B.23}$$

$$\dot{\varrho} = \frac{\dot{\bar{y}}_\phi + \bar{y}_\phi \mu}{M_p^2} \tag{B.24}$$

$$\hat{\varrho} = \frac{\hat{\bar{y}}_\phi - \bar{y}_\phi / y}{M_p^2} \tag{B.25}$$

$$\mu = \frac{\dot{\rho}}{\rho} \tag{B.26}$$

$$\dot{\mu} = \frac{(\partial_u^2 |\nabla \eta|) |\nabla \eta| - (\partial_u |\nabla \eta|)^2}{|\nabla \eta|^2} - \frac{\ddot{\theta}}{\tan \theta} + \frac{\dot{\theta}^2}{\sin^2 \theta} - \frac{\ddot{x}x - \dot{x}^2}{x^2} \tag{B.27}$$

$$\begin{aligned}
\dot{\mu} &= \frac{(\partial_\eta \partial_u |\nabla \eta|) |\nabla \eta| - \partial_u |\nabla \eta| \partial_\eta |\nabla \eta|}{|\nabla \eta|^2} - \frac{\dot{\theta}}{\tan \theta} + \frac{\dot{\theta} \ddot{\theta}}{\sin^2 \theta} - \\
& \frac{\dot{x}x - \dot{x}^2}{x^2}
\end{aligned} \tag{B.28}$$

$$\gamma = \frac{\check{\rho}}{\rho}. \tag{B.29}$$

Danksagungen

Zu aller erst möchte ich meinem Doktorvater Prof. Dr. P. L. Biermann für das Thema dieser Arbeit und die unermüdliche Unterstützung danken, ohne die diese Doktorarbeit niemals zu Stande gebracht hätte. Er gewährte mir die große Freiheit, mich auf dem Gebiet der magnetischen Sternwinde nach eigenem Willen auszutoben, ohne daß er das Interesse an mir und meiner Arbeit verlor und mich mit ihr alleine gelassen hätte. Sein steter Rat war für mich immer ein Ansporn und ein wichtiger Wegweiser durch das manchmal doch recht unübersichtliche Terrain der Astrophysik.

Mein Dank gilt auch Prof. Dr. H. J. Fahr für sein Tätigkeit als Gutachter für diese Dissertation.

Dem Max-Planck-Institut für Radioastronomie danke ich für den mir zur Verfügung gestellten Arbeitsplatz samt der komfortablen EDV-Ausstattung, die einem Theoretiker wie mir das Leben so viel einfacher macht. Hier gilt mein besonderer Dank H. G. Girnstein und Dr. P. Müller. Außerdem danke ich dem Institut für die langfristige finanzielle Unterstützung, die mir die Freiheit gegeben hat, meinem Forscherdrang ungehindert nachzugehen. Dies gilt auch für die großzügige Unterstützung durch die Studienstiftung des deutschen Volkes.

Ganz wichtig für das Gelingen dieser Doktorarbeit war auch die wunderbare Arbeitsatmosphäre, die ich meinen Arbeitskollegen Alina & Fänel Donea, Torsten Enßlin, Dr. Heino Falcke, Dr. Wolfram Krüß, Dr. Chunyu Ma, Dr. Biman Nath, Dr. Martina Niemeyer, Giovanna Pugliese, Dr. Jörg Rachen, Iliya Roussev, Yiping Wang und Christian Zier verdanke. Sie haben dafür gesorgt, daß die letzten vier Jahre eine wunderschöne Zeit waren, an die ich immer gerne erinnern werde. Speziell danken möchte ich Dr. Heino Falcke für die Einführung in die Geheimnisse der Unix-Welt, Dr. Wolfram Krüß für die Idee, Wellen in magnetischen Sternwinden zu untersuchen, und Torsten Enßlin für die gewissenhafte Durchsicht dieser Arbeit. Mein Dank gilt auch meinen Freunden außerhalb der Astronomie, die mich immer wieder daran erinnerten, daß es auch ein Leben außerhalb der Astronomie gibt.

Ganz wichtig war für mich natürlich auch die Unterstützung durch meine Eltern und meine ganze Familie, die mir erst meinen Lebensweg und damit auch diese Doktorarbeit ermöglicht haben. Sie haben nie den Glauben an mich verloren haben und immer unendliche Geduld mit mir bewiesen.

Lebenslauf

Name		Henning Seemann
Geburtsdatum/-ort		28.01.1969 in Lüneburg
Nationalität		deutsch
Familienstand		ledig, kinderlos
Schulbildung	08/75 - 01/77 02/77 - 07/79 08/79 - 06/81 07/81 - 07/85 08/85 - 06/88	Grundschule in Lüneburg Grundschule in Gelnhausen Gymnasium in Gelnhausen Gymnasium in Dortmund Gymnasium in Braunschweig Abschluß mit Abitur
Wehrdienst	07/88 - 09/89	
Studium	10/89 - 08/92 10/91 09/92 - 05/93 10/93 - 03/94	Studium der Physik, Universität Bonn Vordiplom Hauptstudium der Physik, Graduate School, University of Wisconsin, Madison, USA Hauptstudium der Physik, Universität Bonn und Suche nach einer Doktorarbeit
Studienabschluß	05/93	Master of Science, Physics (Madison)
Promotion	04/94 - 03/98	Doktorarbeit am Max-Planck-Institut für Radioastronomie, Bonn
